# Ecosystem Protection in a Sustainable World:

## A Challenge for Science and Regulation

15–19 May 2011

abstract book

SETAC

# ABSTRACT BOOK
# SETAC EUROPE 21ST ANNUAL MEETING
# TABLE OF CONTENTS

This book composes the abstracts of the presentations for the platform and poster sessions of the 21st Annual Meeting of the Society of Environmental Toxicology and Chemistry (SETAC), conducted at the Milano Convention Centre in Milan, Italy from 15-19 May 2011.
The abstracts are reproduced as accepted by the Scientific Committee of the 21st Annual Meeting and appear in order of abstract code, in alphabetical order per presentation type. The poster spotlight abstracts are included in the list of poster abstracts. The presenting author of each abstract is underlined.

# SOCIETY OF ENVIRONMENTAL TOXICOLOGY AND CHEMISTRY

In the 1970s, no forum existed for interdisciplinary communication among environmental scientists, biologists, chemists, toxicologists, and others interested in environmental issues such as managers and engineers. The Society of Environmental Toxicology and Chemistry (SETAC) was founded in 1979 to fill the void. Based on growing membership, meetings attendance, and publications, the forum was needed.

A unique strength of SETAC is its commitment to balance the interests of academia, business, and government. The Society by-laws mandate equal representation from these three sectors for World Council Officers, Board of Directors / Council Members, and Committee members. And although there is no control mechanism, the proportion of members from each of the three sectors has remained nearly equal over the past 30 years.

Like many other professional societies, SETAC publishes esteemed scientific journals and convenes annual meetings replete with state-of-the-science poster and platform presentations. Because of its multidisciplinary approach, however, the scope of the science of SETAC is much broader in concept and application than that of most other societies.

SETAC is concerned about global environmental issues. Its members are committed to good science worldwide, to timely and effective communication of research, and to interactions among professionals so that enhanced knowledge and increased personal exchanges occur.

SETAC was founded in North America but membership was open to environmental scientists worldwide. SETAC Europe was organized in 1989; SETAC Asia / Pacific in 1997 and SETAC Latin America in 1999. Members voted overwhelmingly in 2001 to combine these "geographic units" into one global society to form the SETAC World Council. SETAC meets the professional needs of individuals at local and regional levels throughout all geographic units, throughout national branches and chapters (Argentina, Brazil, United Kingdom, Central and Eastern Europe, Africa and soon-to-be organized Japan), through regional chapters, and through national language branches (Germany). International acceptance of the SETAC model continues with widespread interest in Russia and Africa. It is now the job of SETAC World Council to oversee the myriad SETAC activities around the world and to assure the integrity of the Society.

*Environmental Toxicology and Chemistry*, an internationally acclaimed scientific journal, has grown from a quarterly publication of fewer than 400 pages annually in 1982 to a monthly publication of 2.915 pages in 2001. Since January 2005, SETAC publishes a second scientific journal: *Integrated Environmental Assessment and Management*. IEAM is devoted to bridge the gap between scientific research and the use of science in decision making, regulation and environmental management. SETAC publishes the global newsletter SETAC Globe, peer-reviewed workshop and symposia proceedings, and a variety of technical reports.

# Keynote speaker abstracts

**Ecotoxicology examined: current issues and trends**
Ryszard Laskowski
Jagiellonian University, Kraków, Poland
In the second half of 20th century ecotoxicology developed to a large extent through "jumping" from one urgent issue to another. We had thus the bioconcentration and biomagnification boom in 1970s through 1980s, standardization of ecotoxicological tests took our minds mostly in 1990s, and we entered 21st century diving enthusiastically into the 'omics'. While this picture is probably typical for any young science, the grown-up fields let the scientists harvest many crops. I believe that ecotoxicology is just entering its maturity. Hence, when asked by the conference organizers to give a plenary lecture on "New trends in ecotoxicology", I realized that it is not as easy to identify them today as it used to be in the past. The 'omics' is still with us but can hardly be called now the "new trend". At the same time, we have come back to problems noticed already years ago, like toxicity of complex mixtures and influence of natural factors on toxic effects of pollutants. We are also looking beyond simple standard tests and urge the decision makers to consider more elaborate methods of ecological risk assessment. Not being quite sure whether this is just my personal viewpoint – possibly a reflection of loosing the track? – I made a short poll among colleague ecotoxicologists. The result was the same: none (sic!) of the responders was eager to name just one novel trend, and the responses were widely spread across different topics. Almost equal number of researchers found the most important issues in toxicokinetics and toxicodynamics, landscape and ecosystem ecotoxicology, interactions between chemicals and natural factors, population-level modeling, or chemical mixtures. Further topics included nanoparticles – the only problem that can be indeed called reasonably novel, and methods for extrapolating results of laboratory tests to real-field scenarios. Is that a bad sign that top scientists are not able to identify novel trends in the subject of their interest? I do not think so: as mentioned above, I believe that this is the sign of maturation (of ecotoxicology, not the scientists...). Despite the difficulty with naming novel issues, there are, however, some very interesting trends and processes undergoing in ecotoxicology nowadays, certainly deserving a closer look and a discussion. Among them are both purely scientific ones and societal, and both groups will be addressed in my lecture.

**Ecosystem services, environmental protection and SETAC: preventing and adapting to the "perfect storm"**
Lorraine Maltby
University of Sheffield, Sheffield, United Kingdom
Ecosystems provide us with the essentials for life – food to eat, water to drink, fibre for clothes and shelter, fuel to keep us warm. However, they do more than that; they play a key role in climate regulation through carbon sequestration, flood prevention through water retention and runoff regulation, and water purification through filtration processes and microbial activity. They are places where we go to relax, to participate in recreational activities or simply to be inspired by the wonders of the natural world. Moreover, ecosystems perform essential processes such as nutrient and water cycling and the production of biomass. These benefits to people are termed ecosystem services and they are provided by all ecosystems.
The growing human population is putting increased pressure on ecosystems and their ability to provide the services we require. It is estimated that by 2030, world food demands will increase by 50%, energy demands will rise by 50%, water demands will increase by over 30% and 60% of the world's population will live in urban areas. Overlay climate change and you have the ingredients for what was described by John Beddington, the UK government's chief scientist, as the "perfect storm".
Managing landscapes for the provision of the ecosystem services we require (e.g. food, water, energy, minerals), whist at the same time protecting the biodiversity on which many of these services depend, is a major challenge, but one to which the SETAC community can make a valuable contribution. This keynote presentation will consider this challenge and the opportunities it provides for environmental scientists.

**Exposure science - the link between hazard and risk**
Marika Berglund
Institute of Environmental Medicine, Karolinska Institutet, Stockholm, Sweden
We are facing the challenge of assessing the exposure to a huge number of chemicals and other stressors. Exposure science is the platform for generating better exposure information which is highly needed for reliable risk assessment and protection, prevention and sustainability of the environment and human health. The lack of relevant exposure information is often a problem in regulatory decision-making and risk reduction. Development and harmonization of methods for characterizing, estimating, modelling, measuring, and quantifying exposure will result in more efficient risk reduction in the future. Toxicologists, epidemiologists, environmental and human health scientists, risk assessors and risk managers are all using a number of different data sources and methods to estimate and analyse exposure information. It is time to start working together, and to learn from each other. Together we can identify data gaps and shape the future of exposure science for more reliable decision-making. Exposure science is the crucial link between hazard information and risk. It has a great potential to meet the need for suitable methods to obtain the exposure information required by new chemical legislations and regulatory frameworks.

**Toward sustainable solutions**
Robert Costanza
Institute for Sustainable Solutions, Portland State University, USA
A high and sustainable quality of life is a central goal for humanity. Our current socio-ecological regime and its set of interconnected worldviews, institutions, and technologies all support the vision of unlimited growth of material production and consumption as a proxy for quality of life. However, abundant evidence shows that, beyond a certain threshold, further material growth no longer significantly contributes to improvement in quality of life. Not only does further material growth not meet humanity's central goal, there is mounting evidence that it creates significant roadblocks to sustainability through increasing resource constraints (i.e., peak oil, water limitations) and sink constraints (i.e., climate disruption). Overcoming these roadblocks and creating a sustainable and desirable future will require an integrated, systems level redesign of our socio-ecological regime focused explicitly and directly on the goal of sustainable quality of life rather than the proxy of unlimited material growth. This transition, like all cultural transitions, will occur through an evolutionary process, but one that we, to a certain extent, can control and direct through the process of shared envisioning. Visions and models of integrated sets of worldviews, institutions, and technologies are needed to stimulate and seed this evolutionary redesign. The process of creating a shared vision of the future is also a key element of real democracy.

## SS01 - New QSAR models for regulatory purposes

**SS01-1**

**Consensus Modeling of Environmental Endpoints**

T Martin, DM Young
US EPA, CINCINNATI, United States of America

A consensus modeling approach was devised to develop models for different ecotoxicological endpoints of large, structurally diverse data sets. In the consensus approach, the endpoint is predicted by taking the average of the predicted values from several different QSAR (quantitative structure-activity relationship) approaches. Several QSAR approaches were used in the consensus model including the hierarchical clustering, multilinear regression, group contribution, and nearest neighbor methods. Models were developed for the following endpoints: acute aquatic toxicity, acute oral rat toxicity, fish bioaccumulation factor, and Ames mutagenicity. In general the consensus models achieved higher prediction accuracy and prediction coverage (the fraction of chemicals predicted) than any of the individual models by themselves.

**SS01-2**

**The development of new tools towards a better exploitation of non testing methods for regulatory purposes**

A Roncaglioni, A Manganaro, R Gonella Diaza, A Lombardo, M Petoumenou, E Benfenati
Istituto di Ricerche Farmacologiche Mario Negri, MILAN, Italy

The use of non testing methods, including QSAR and read-across approaches, has the potential ability to obtain fast, costless and reliable data, hence their usage has been promoted in the regulations.
Some difficulties are anyhow experienced in the use of these methods particularly by non experts to properly address the reliability of the estimations so obtained.
For instance more details about QSAR models may be provided, including information about the meaning of the outputs obtained by the models, the applicability domains of models, and the source data that the models are based on.
Here we present methods to fill these information gaps, offering tools to examine the results, their meaning, and the possible uses of the models.
Compared with many existing QSAR models, we have put greater emphasis on ensuring that the models generate transparent, understandable, reproducible and verifiable results. To achieve this, a series of tools has been optimised, which can relate the results obtained for the target chemical to the results obtained for similar (structurally related) compounds.
In addition to obtaining the result of the evaluation, the models we studied provide the user with access to a series of features that are important for regulatory purposes:
* an identification of the possible regulatory uses of the result produced;
* an evaluation of the applicability domain, with an explanation;
* an understanding of the rules and reasoning behind the model.
Moreover these tools also provide a reproducible procedure for read-across.
Acknowledgments: Support by EU projects ANTARES (LIFE programme, project ref. LIFE08 ENV/IT/000435) and ORCHESTRA (FP7-COOPERATION programme, contract nr. 226521) is acknowledged.

**SS01-3**

**Integrating statistical and structural results in predictive modelling for a multi-view evaluation**

C Gini, T Ferrari, D Cattaneo
Politecnico di Milano, MILANO, Italy

The application of new rules and regulations calls for a more efficient in-silico screening. In particular, prioritization, classification & labelling, and prediction open new challenges. The modelling systems will need to be accurate and understandable. Either QSAR or SAR are often used alone to model the activity of substances, on the basis of the kind of the output (dose vs presence) property of interest. Many QSAR models are simple or complex relations built over molecular descriptors. The choice of the descriptors to use is relevant since it affects the statistical accuracy of the model; moreover a lot of effort is put in justifying the choice in terms of interpretability of the model (or in terms of mechanicistic steps). Many SAR models are manually built from a set of observations and experiments and consist in a set of rules, usually stated as structural alerts that have been associated with the property. It is not easy to go from a qualitative SAR result to a quantitative QSAR result. On the other hand, the structural nature of chemicals can be explicitly considered by a graph-mining approach, which mines large datasets for frequent substructures, or fragments, that are statistically associated with the property.
We present a new approach that integrates the two SAR-QSAR methods. It can be used to build statistical models using categorical or continuous values, can derive structural alerts, can produce hypotheses of safe substructures, and can accompany the statistical result with a rule.

**SS01-4**

**Towards the application of Nano-QSAR models for regulatory purposes**

T Puzyn[1], D Leszczynska[2], J Leszczynski[2]
[1]University of Gdansk, GDANSK, Poland
[2]Interdisciplinary Center for Nanotoxicity, Jackson State University, JACKSON, MS, United States of America

The REACH legislation in Europe governs inventory of chemicals that are introduced at the market in large quantities. Every new chemical should be registered first, and the registration must be precluded by a comprehensive risk assessment. The REACH system promotes the use of alternative ways of toxicity testing, including Quantitative Structure-Activity Relationship methods. When properly validated, QSAR models can replace costly and ethically questionable experiments with use of laboratory animals.
Regarding the extensive growth of nanotechnology observed during last few years nanomaterials are becoming a distinct group of widely used chemicals. Since nanoparticles differ from bulk substances by physicochemical properties and toxicity, the registration requirements for them should be reviewed and adapted considering their specificity.
This presentation reviews current status of nanomaterials under the REACH regulation and discusses advances and challenges of QSAR development for nanomaterials (Nano-QSAR). The most challenging problems are: (i) scarce and/or inconsistent experimental data available and lack of conceptual frameworks for grouping nanoparticles according to mode of physicochemical properties and toxic action; (ii) lack of appropriate descriptors able to express specificity of "nano"structure; (iii) very limited knowledge on the interactions between nanoparticles and biological systems (DNA, proteins, membranes etc.); and (iv) lack of rational modeling procedures to screen large numbers of structurally diversified nanoparticles. Majority of the existing Nano-QSARs refer to physical-chemical enpoints. However, our last contribution demonstrated the first Nano-QSAR model for predicting toxicity (cytotoxicity to bacteria E. coli) of nanosized metal oxides. This would be the first step towards creating a comprehensive tool for computational risk assessment of nanomaterials to be used for regulatory purposes.

**SS01-5**

**Regulators' role and mission: Feedback from various stakeholder contexts**

M Mays[1], E Benfenati[2], R Knauf[3], S Pardoe[4]
[1]Institut Symlog, PARIS, France
[2]IRFMN, MILANO, Italy
[3]Federchimica, MILANO, Italy
[4]PublicSpace Ltd., ULVERSTON, United Kingdom

The ORCHESTRA project (2009-12, EC #226521) aims to promote wider understanding, awareness and appropriate use of in silico methods. The project web portal will become a central resource for sharing of knowledge and experience and will also provide downloadable software.
In September 2010, we consulted regulators, scientists and industry stakeholders on their use of and perceptions of in silico methods (see our poster presentation for details; view questionnaire and fill out online at www.in-silico-methods.eu)
While the self-selected sample was very restricted, among the points of interest are the positions taken by regulators, compared to or contextualized by those of other stakeholders. For instance, regulators appear to have tested in silico methods in a distinctly broader array of areas (with human toxicology leading the field - in particular contrast to industry experience).
Regulators experiment with in silico methods for the full variety of functions these may serve, ranging from a formal decision focus (supporting information, or weight-of-evidence input), to less formal convenience features (fast evaluation of chemical properties). Use of these decision aids is expected to grow, most strikingly for the prioritisation of compounds for further analysis, and as input to the "key study".
Outstanding is the gap between perceptions by scientists and industry users, and by regulators, regarding benefits of in silico methods. Regulators surveyed give little emphasis to in silico's ability to reduce laboratory use of vertebrates (in stark contrast also to lay demands as judged by an informal tracking of press articles about REACH.) One regulator commented: "Reduction of vertebrate testing is a major goal, however, it is secondary to improved risk management". Do regulators thus weigh the benefits strictly in regard to their weighted priorities (goals)? In this way, regulators' primary evaluation of in silico would be (appropriately) in terms of whether it is "fit for purpose". Is that purpose, however, centred for regulators on absolute human and environmental protection, or on optimisation of risk management?
Do other stakeholder categories take for granted that regulators' role is the absolute protection of humans (leaving thus a margin for demands of animal protection as well)? Is optimisation understood? Insight is offered from the area of nuclear power and radioactive waste - where major studies have focussed on societal demands on regulation.

## SS02 - International reference life cycle data system (ILCD) handbook and data network

**SS02-1**

**LCA and the ILCD in the context of Sustainability Assessment**

C Ciupagea
European Commission, ISPRA, Italy

The new Unit 'Sustainability Assessment' of the Institute for Environment and Sustainability of the European Commission's Joint Research Centre (JRC) is intended to provide scientific and technical support to EU services that are engaged in enhancing sustainable development and resource efficiency.
It will develop and apply new approaches and solutions to integrated socio-economic and environmental assessments and impact analyses across policies at local, regional and global scales in a customer-driven manner.
The deliverables will equally help industry and other actors of society to actively work on the improvement of their products and daily operations as well as advice procurers and citizen towards more sustainable consumption.
A core component and expertise of the new Unit is related to the life-cycle thinking concept and, in particular, to the (environmental) Life Cycle Assessment (LCA). This Special Symposium focuses on the development of the International Reference Life Cycle Data System (ILCD) Handbook and Data Network. The ILCD has been developed in context of the European Platform on LCA to support life cycle based policies and business instruments related to sustainable production and consumption as well as resource-efficiency with guidance and with consistent and quality-assured data. Very important next to the tool LCA itself are the concepts and principles that make up the strengths of LCA, which plays a double role both as one specific method and component in the sustainability toolbox and inspiring a wider sustainability assessment with the named concepts and principles it draws on. The presentation will briefly place LCA into the wider integrated sustainability assessment framework envisaged for the current and future work of this new Unit

**SS02-2**

**The role of the ILCD Handbook as methodological basis for robust life cycle based environmental policies**

M Galatola
European Commission, DG Environment, BRUSSELS, Belgium

**SS02-3**

**Overview of the International Reference Life Cycle Data System (ILCD)**

MA Wolf, R Pant, K Chomkhamsri, DW Pennington, S Sala, M Brandao
European Commission, Joint Research Centre, ISPRA, VA, Italy

The International Reference Life Cycle Data System (ILCD) has been developed as ISO-conform but further specified guidance on Life Cycle Assessment (LCA) and to facilitate access to quality-assured Life Cycle Inventory (LCI) data. This is in response to the Integrated Product Policy (IPP) Communication and to support the implementation of sustainable production and consumption as well as resource efficiency policies in the EU and internationally. The ILCD consists primarily of a Handbook and a Data Network: The ILCD Handbook is a series of technical

guidance documents that provides the basis for developing consistent and quality-assured life cycle data and assessments. The upcoming decentralised ILCD Data Network provides access to ILCD Handbook-consistent and quality-assured Life Cycle Inventory data sets. It is open to all providers globally, such as businesses, national LCA projects, researchers, consultants. The data owners maintain their own data and give access via their own servers, based on their own license conditions. To ease the build-up phase, initially also data that meets only the less demanding 'ILCD Data Network - entry-level requirements' can be published via the network. These data are to be ISO-conform and be properly documented and independently reviewed as well as use the common ILCD elementary flows; the next step is to move to fully consistent data. As a foreseen contribution to the ILCD Data Network the European Reference Life Cycle Database (ELCD) is available, covering core LCI data relevant to the European market.
The ILCD has been developed in coordination by the European Commission's Joint Research Centre (JRC), Institute for Environment and Sustainability (IES) together with Directorate-General Environment and through a series of invited and public consultations with global outreach. This has aimed at best-attainable consensus, reflecting best available practice in industry and government. The invited consultations have involved UNEP, the 27 EU Member States, the national LCA projects of Brazil, China, Japan, Malaysia, Thailand and Japan, consultation with the U.S. EPA, a range of industry associations, as well as representatives of leading life cycle database, software and impact assessment method developers.

**SS02-4**
**Steel industry requirements on the methodological basis for life cycle assessment - the role of the ILCD Handbook and Data Network**
C Broadbent
Worldsteel Association, BRUSSELS, Belgium

**SS02-5**
**Plastics industry needs for a common method basis in life cycle assessment for Eco-profiles and Environmental footprinting - the role of the ILCD Handbook and Data Network.**
A Schanssema
PlasticsEurope, BRUSSELS, Belgium
In 1990 the predecessor of PlasticsEurope, the Association of Plastics Manufacturers Europe (APME) decided to develop detailed LCI datasets for processes operated by its member companies with the firm intention of making this information available for public use. It currently has about 70 datasets for intermediates, polymers and some specific polymer products freely available.
The datasets are European industry averages and cover the major proportion of the production in Europe, in some cases the sample size is even up to 100%. These cradle-to-gate LCI datasets - which are called eco-profiles - are compiled by independent consultants, and updated when needed. In 2007 the program was extended with a Product Category Rule for Environmental Product Declarations, in total 10 EPD's were developed. In the meantime PlasticsEurope became the data provider for 25 chemical intermediates and polymers to the European LCA Platform operated by the JRC. The aim of the Platform is to provide a pragmatic standardized toolbox for life cycle supported policy making towards sustainability.
The eco-profiles provide data on fuel and raw material consumption, emissions into air and water and waste generation, the EPD's convert these data into impacts in categories such as abiotic depletion of fuel and elements, global warming, acidification, eutrification, ozone depletion and ozone creation potentials.
In 2008 PlasticEurope decided to organize a public consultation on its methodology document. With inputs from academia, LCA practitioners and the JRC a revised document was prepared which actually was a merger of the original methodology document and the PCR. One of the key objectives of updating this methodology was to achieve the next level of quality by making it more transparent and prescriptive, and to make it "consultant proof"in order to allow different qualified external consultants to compile the LCI datasets. One of the points of critique on the eco-profiles is the lack of an external review. Triggered by the ILCD developments of which the PlasticsEurope dataset will become part, an external review will be included and reported.
After having updated 2 eco-profiles using the improved methodology an accelerated program will be developed to update as much as needed the eco-profiles. Details on the program and how the updating is organized will be explained at the symposium.

**SS02-6**
**Environmentally friendly vehicle design throughout the life cycle - expectations on the ILCD Handbook and Data Network**
S Krinke
Volkswagen AG, WOLFSBURG, Germany
Life cycle assessment (LCA) is a powerful tool which supports life cycle management. It can be used as an environmental management instrument within the product development.
For successful life cycle management the formal incorporation of life cycle thinking into the company policy is a necessary pre-requisite. Additional success factors which have to be met are the transformation of LCA results into measurable targets for engineers. Based on given environmental targets, such as a certain target value for greenhouse gas emissions, LCA can be used to calculate a specific technical target such as the weight of a component, the fuel consumption of a vehicle or the minimum amount of recycled content in a product. The transformation of pure LCA results into measurable technical targets, which can be understood by engineers, will clearly show the added value which LCA can give in terms of life cycle management.
Even for very complex products with a huge variety of different materials and a complex value chain life cycle assessment can be performed with a reasonable time demand, with good quality and integrated efficiently into business processes.
Essential for Volkswagen is that LCA can be fully integrated into internal processes, that the duration of analysis and resource demand for using the tool is reasonable, and of course that it leads to reliable and stable recommendations. Acceptance by customers, government and other stakeholders is equally important. In this context, Volkswagen welcomes the development of the International Reference Life Cycle Data System (ILCD) Handbook, while we also see the need to further operationalize its use in product and sector specific manuals, to be more time and cost efficient in daily routine work. The related ILCD Data Network is understood to help in future to increase the availability of consistent and quality general background data, where such cannot be obtained through the supply-chain, which is the preferred mechanism for Volkswagen.

## SS03 - Marine antifouling - perspectives and recent developments

**SS03A-1**
**Regulatory aspects on antifouling products in the EU.**
KA Haglund
Swedish Chemicals Agency, SUNDBYBERG, Sweden
Antifouling products are regulated within the EU through the Biocidal Products Directive 98/8/EC. An overview will be given on how this regulation works and what types of products are regulated or may fall outside the scope of the Directive. The current state of the art regarding the review of new and existing antifouling active substances will be given. The Directive is now more than 10 years old and will be replaced by a new Biocidal Products Regulation. Updated information on the advancements of this process and possible implications on how the regulation of antifouling products may be affected will be given. Some examples of alternative solutions for keeping fouling away will also be presented.

**SS03A-2**
**Recent developments in antifouling paints, the industry perspective**

**SS03A-3**
**The next generation antifouling-Selektope®**
M Lindblad
I-Tech AB, GOTHENBURG, Sweden
There is a vast range of attempts in finding new antifouling substances with lesser environmental impact. At the same time, the industry demands for sustained antifouling performance are ever increasing in order to minimize fuel consumption and consequently, minimize green house gas emissions. Balancing emissions to the sea and emissions to the air is a delicate optimisation process which involves different aspects where one is marine ecotoxicology. Human risk assessment, regulatory compliance and safe manufacturing are equally important issues. Among those different factors, efficacy are the overall most important factor.
Efficacy can be met by different means, either by killing the organisms or using specific biological cues. Lethal doses are in general high but an alternative is to take advantage of the biology itself which demands a deeper knowledge. This can be used to develop targeted technologies to decrease harmful emissions to the sea without compromising with efficacy.
Selektope® is a new antifouling substance taking advantage of the barnacle biology. Selektope activates specific receptors and interferes with larval behavior at the surface. The larva's attempt to attaching itself to the surface becomes interrupted by Selektope. The effect on the larval behavior is reversible and allow for larval settlement on untreated surfaces.
The specific mode of action allows for low concentration of Selektope. To avoid barnacles, a 0.1% in marine paint is sufficient and should be compared to 3-5% of other organic biocides and 30% or more of cuprous oxide. Further, the specificity is also an advantage in the overall risk assessment regarding regulatory compliance. The different risk assessments will be driven by reversible receptor specific end points. General toxicity appears in concentrations far above the efficacy concentration and is therefore of less concern. Further, it has the advantage of being degradable and demands less resources in a life cycle perspective.
Selektope is now under BPD evaluation. The dossier contains environmental risk assessment, human risk assessment, chemical risk assessment and efficacy evaluation. The risk assessments are based on more than 60 performed studies, both university performed and regulatory compliant studies.
To secure efficacy, paint companies are performing static and dynamic long term efficacy studies. Presently, a number of ocean going vessels have test patches on their hulls containing Selektope.

**SS03A-4**
**Recent developments on the Chinese market**

**SS03B-1**
**Ecotoxicology of antifouling biocides**
H Blanck
University of Gothenburg, GÖTEBORG, Sweden
Fouling of ship hulls has been a problem to seafarers since Noah´s Ark. The development of TBT-copolymers in the 1960´s stabilized the antifouling market with highly efficacious coatings for both pleasure craft and merchant fleet. The awareness of TBT-related ecological effects particularly on gastropods in the early 80´s caused a deep reconsideration of antifouling strategies. Biocide-free fouling release coatings were developed, while copper came to dominate the biocide-containing paints. A variety of so-called booster biocides, with different efficacy profiles and mechanisms of action, were introduced to be able to formulate completely fouling-protected coatings. In the 2000´s a high number of organic booster biocides were used in Europe, many of them detectable in coastal surveys. Several of them were later questioned from environmental reasons. The balance between efficacy and risk thus remains a key issue.
It is a dilemma that fouling organisms are antifouling targets when occupying a ship hull, but non-target organisms in their natural habitat. Both efficacy and risk is always strongly related to the toxicity of the biocide. In highly efficacious coatings there is a complete toxic effect to all fouling organisms at or near the ship hull surface. To avoid ecological consequences, this toxicity must be lost before it reaches the biological constituents of the aquatic environments. Readily degradable antifouling compounds and a well-balanced, controlled release without overdosing are therefore crucial. In any biocidal paint it is essential that the high toxicity to fouling organisms on the ship hull is not allowed to be expressed also in the ecosystem. A highly relevant biological aspect - development of tolerance - has recently been put into the European Biocide Regulation as an item to consider in approval of biocidal products. Acquired tolerance of the target organisms will require changed paint formulations that increase release and thus loading to the ecosystems. In this way the area and intensity of detrimental effects is increased. In areas polluted with antifouling biocides, tolerant strains or communities are regularly observed, thus indicating an anthropogenic selection pressure on biota.

**SS03B-2**
**Environmental occurrence and fate of antifouling biocides**
V Thomas
NIVA, OSLO, Norway
Antifouling biocides are the active ingredients in antifouling paints that prevent the adhesion and growth of organisms to a painted surface. A wide range of chemicals are used as antifouling biocides which have very different physico-chemical properties and therefore differing environmental fates, behaviour and effects. For biocides that have been widely used over a number of decades, for example Irgarol 1051 and diuron, there are a large amount of public domain environmental data, including for their respective metabolites that allow for their environmental safety and potential risk to the environment to be assessed. For other biocides such as dichlofluanid,

DCOIT and zinc/copper pyrithione there is a good understanding of their fate and effects, however few monitoring studies have been performed and not so much is known about the fate and effects of their metabolites. Finally there are new or candidate biocides such as triphenylborane pyridine (TPBP) and medetomidine for which there is very little public domain information. This presentation will provide an overview of the public domain fate and occurrence data available for biocides highlighting some of properties that influence the risks associated with the use of certain biocides.

**SS03B-3**

**Employing classical mixture toxicity concepts for the optimization of biocide combinations for antifouling paints**

T Backhaus, Å Arrhenius, A Hilvarsson, K Holm, I Wendt, H Blanck
University of Gothenburg, GOTHENBURG, Sweden

The classical mixture toxicity concepts of Concentration Addition (CA) and Independent Action (IA) have been successfully used in the past for modeling the joint action of pesticides, pharmaceuticals and other biologically active compounds. Here we report on their application for the environmental optimization of biocide combinations for antifouling purposes. Both concepts make use of efficacy data of individual compounds and allow the prediction of the total efficacy of all possible mixtures that can be composed from a given set of compounds. This enables a systematic and unbiased in silico exploration of the complete space of possible combinations.
By applying a risk weighting function that accounts for the environmental risks of each individual compound in each mixture it is then possible to rank the mixtures according to their predicted total environmental risk. This provides a detailed map for selecting the most promising combinations for further studies, e.g. for field tests.
The developed algorithms were applied to a set of 7 common and novel antifouling biocides. We experimentally recorded their individual toxicity and efficacy for representatives of the most common fouling organisms (Barnacles, Mussels, Sea Squirt, Bryozoans, Sea Lettuce and Biofilms (slime)) and then modeled the joint efficacy of all possible combinations of the 7 biocides. All combinations with a sufficient efficacy (at least 99% effect on the settling of each test organism) were then ranked according to their modeled environmental risk. We will present the results of this optimization procedure and will relate the efficacy of the modeled mixtures to their environmental risks. In particular we will highlight whether and to what extent combination products can be expected to have lower environmental impacts than products with only one or a limited number of active ingredients, while still providing the same efficacy. The study is part of the Swedish Marine Paint program which is sponsored by Mistra, the Foundation for Strategic Environmental Research.

**SS03B-4**

**Towards novel marine paints with controlled release of biocides - concepts and applications**

ML Andersson, A Mok, A Movahedi, M Nordin, L Nordstierna, M Nydén
Chalmers University of Technology, GOTHENBURG, Sweden

The growth of microorganisms, on painted surfaces and other coatings in general and on ship hulls in particular, has increased during the last decades as many anti-growth agents have gradually been prohibited due to toxicity. The current standard way of using biocides in protective coatings against micro-organic surface growth is insufficient as the biocide leaks out from the coating too fast. As most biocides are small molecules, the size results in a fast diffusional leakage and the coating protection is rapidly lost. A new generation of antifouling coatings is therefore needed as most antifouling principles suffer from poor efficacy or pose environmental problems. We investigate a method for prolongation of the coating protection by reducing the release rate of biocides in a controlled manner. This can be achieved by the use of encapsulated biocides in the paint. The biocides are residing in micrometer-sized reservoirs, microspheres, and are subsequently slowly distributed into the coating. The encapsulation procedure results in a high process yield as well as a high loading capacity. So far, uncharged hydrophobic biocides have been successfully encapsulated. Laboratory experiments were designed to provide information of the release rate of various biocides, recorded by various analytical techniques, from painted surfaces in artificial seawater. It was shown that the release is considerably slower from coatings with microspheres compared to an ordinary formulation with freely dispersed biocides. Experimental data were compared to models describing the release by a diffusion mechanism out from spherical particles. The findings have increased our understanding of important parameters in the microsphere design with regard to tuning the release behavior. Further tuning of the release is the focus of two new projects comprising incorporation of nanoclays in the particles and modification of the particle surface using polyelectrolyte layer-by-layer assembly. Considerably comprising field test is due 2010-2011 where we study the effect of fouling on various paint/biocide formulations that have been selected based upon the collective results from the Marine Paint Programme. Microspheres might thus be a beneficial tool for the development of coatings, with a longer protection against biofouling, since they allow for optimization of biocide concentrations. They also increase the lifetime of the protective coating independent on the type of paint system used.

## SS04 - Waste treatment in a sustainable world. State-of-the-art and perspectives

**SS04-1**

**Nanomaterials as emerging contaminants at global scale**

DB Barcelo, JS Sanchis, MF Farre
IDAEA-CSIC, BARCELONA, Spain

Nanotechnology is a major innovative scientific and economic growth area and is fast becoming one of the major areas of chemistry. Its appeal lies in the long-dreamt-of ability to investigate and to manipulate matter at the level of individual atoms and molecules. However, at same time has opened a new window for a wide group of emerging contaminants and a new type of human exposure that needs to be assessed, nanotechnology raises many of the same issues as any new technology, including concerns about the toxicity and environmental impact of nanomaterials, and their potential effects on global economics, as well as speculation about various doomsday scenarios. These concerns have led to a debate among advocacy groups and governments on whether special regulation of nanotechnology is warranted.
In addition, release of manufactured NPs into the aquatic environment is largely an unknown. The surface properties and the very small size of NPs provide surfaces that may bind and transport toxic chemical pollutants, as well as possibly being toxic in their own right by generating reactive radicals.
These questions and the current state of the art on ecotoxicological data will be reviewed together with global applications and industrial development and recent findings for their assessment in the environment. Recent finding in our group for the detection and quantification of fullerenes and dendrimers using analytical methods based on liquid chromatography (LC) coupled to a hybrid triple quadrupole linear ion trap mass spectrometry (QqLIT-MS) for their trace quantification will be exposed. In addition, the results of the investigation of different types of environmental matrices, including air, superficial waters and waste water will be presented. These works constitute the firsts reports on the occurrence of nanoparticles in the environment highlighting the need of nanotechnologies residues assessment for risk evaluation of this materials.

**SS04-2**

**Modelling to assess policy instruments in waste management**

T Ekvall[1], A Björklund[2], ON Eriksson[3], T Forsfält[4], M Ljunggren Söderman[1], Å Stenmarck[1], J-O Sundqvist[1]
[1]IVL Swedish Environmental Research Institute, GÖTEBORG, Sweden
[2]Royal Institute of Technology, STOCKHOLM, Sweden
[3]University of Gävle, GÄVLE, Sweden
[4]National Institute of Economic Research, STOCKHOLM, Sweden

An on-going Swedish research program, Towards Sustainable Waste Management (TOSUWAMA), funded by the Swedish Environmental Protection Agency during 2006-2012, aims at formulating and assessing policy instruments that may contribute to the development of a more sustainable waste management, shifting waste management upwards in the waste hierarchy. The research programme is interdisciplinary and involves the study of many different aspects of waste management: environmental, economic, cultural and psychological. An important part of the assessment is made through soft-linking a set of quantitative models:
- EMEC, a general equilibrium model of the Swedish economy,
- NatWaste, a systems engineering model of the Swedish waste-management system, and
- SWEA, a life cycle assessment model.

This combination of tools is applied to explore how the economy, the waste management sector, and the environment might be affected in the year 2030 by different policy instruments. We use scenario analysis to deal with the large uncertainties inherent in the long-term future: each policy instrument is assessed in five different external scenarios with different assumptions regarding the future development of external aspects of politics, economy, technological development etc. In one scenario, the quantity of Swedish waste continues to rise almost with the economic growth. In other scenarios, the total waste quantity is nearly constant.
An important challenge in this task was to find the appropriate level of detail. The models include municipal as well as most industrial waste flows. We had to make careful decisions on where waste types and economic sectors could and must be aggregated or disaggregated. Another challenge was to link the models in such a way that information generated as output by one tool can easily be used as input by another. This challenge became more severe because the combination of tools has to be flexible enough to be able to assess different types of policy instruments.
We have started assessing economic policy instruments such as a reduction in the VAT of services, tax on waste incineration, tax on raw materials, etc. These all have small effects in the models, compared to the dramatic effects of instruments such as the extended producer responsibility and the landfill bans that are already in place in Sweden.
Further information on our progress and results is posted at the TOSUWAMA website: www.sustainablewaste.info.

**SS04-3**

**A study of WEEE treatment options in Brazil**

CF Mahler[1], MG Araujo[2], A Magrini[3], F Lugli[4]
[1]COPPE/Federal University of Rio de Janeiro, RIO DE JANEIRO, Brazil
[2]PPE Programa de Planejamento Energetico, RIO DE JANEIRO, Brazil
[3]PPE, RIO DE JANEIRO, Brazil
[4]Universidade Federal de Rio de Janeiro, RIO DE JANEIRO - RJ, Brazil

Electrical and electronic equipment is one of the most dynamics sectors of the economy, comprising 4.5% of Brazilian gross domestic product. Although business volumes are high, there is no formal specific structure for treatment of waste electrical and electronic equipment (WEEE) in Brazil. A general law on solid waste was approved by Congress and signed by the president on August 2, 2010, but further enabling regulations still need to be issued.
Despite the lack of WEEE treatment, there is the advantage of the inexistence of informal WEEE treatment like in China, India and Africa, due to the higher cost of labor and transaction costs. Nevertheless, other materials are commonly recycled on Brazil, particularly aluminum cans, where the recycling rate was 96% in 2005. This activity developed completely independent of government actions, starting in the early 1990s.
There is a good opportunity to start a formal WEEE treatment structure from the beginning with the support of scavengers and recyclers for improved dismantling to achieve higher recovery of metals and appropriate treatment of hazardous substances.
Nonetheless, the feasibility of such a structure depends on government incentives, through tax advantages and financial support with lower interest rates for investments. Also, the secondary materials market has an important role in the financial equation. This is particularly true in Brazil where primary metals prices are low, since the country is a big global supplier of several metals for many other countries, like China.
Reduction of use is difficult to perceive. Formal recycling will need a strong support from the government along the next years. Reuse and refurbishment of equipments are reputed to be good strategies for WEEE issue considering the decreasing emissions on manufacturing of new equipments, savings of raw primary materials, and social aspects like employment of labor force and digital inclusion of poor communities.
A risk analysis for an after Solid Waste Nationals Politics implementation scenario must evaluate the possibility of contamination of others waste streams since the learning curve of the WEEE system will take some years to reach a good efficiency. The specific regulation of WEEE must establish quantitative and qualitative monitoring of recycling process, control over output secondary material and final disposal of remaining material.

**SS04-4**

**Risk assessment of water effluents in Catalan (NE Spain) waste-water treatment plants based on E-PRTR data**

A Ginebreda[1], D Guillén[1], E Martínez[1], RM Darbra[2], A Àgueda[2], J Cabanillas[1], D Barceló[1], L Moragas[3], J Robusté[3]
[1]IDAEA - CSIC, BARCELONA, Spain
[2]Universitat Politècnica de Catalunya, BARCELONA, Spain
[3]Agència Catalana de l'Aigua (Catalan Water Agency), BARCELONA, Spain

The Regulation 166/2006 concerning the establishment of a European Pollutant Release and Transfer Register (amending Council Directives 91/689/EEC and 96/61/EC) aims at establishing a Community level register of integrated pollutant release and transfer (known as 'the

European PRTR' or 'E-PRTR'). Its application domain affects certain types of manufacturing and production facilities, among them waste-water treatment plants (WWTPs) with a capacity of more than 100,000 equivalent inhabitants.
Data gathered under the E-PRTR regulation provide a valuable source of information regarding the emission of pollutants to air, water and waste from the assessed installations.
The scenario of the present study covered the 22 WWTP's located in Catalonia (NE Spain) affected by the E-PRTR regulation. 41 micropollutants belonging to different families (heavy metals, anions, volatile organochlorine compounds (VOX), semivolatile organochlorine compounds, volatile aromatic hydrocarbons, policyclic aromatic hydrocarbons, herbicides, endocrine disruptors, phenols and organotins) were determined on water effluent samples (24 h integrated) from the aforementioned plants. Appropriate referenced analytical methods were used to obtain concentration levels of these pollutants during the period 2008 to 2010.
The resulting concentrations were subsequently evaluated using two different risk assessment methods, namely, the COMMPs procedure developed by the Fraunhofer Institut and a method based on fuzzy logic. From the results gathered it has been possible:
(a) To characterize and compare the different sites (WWTPs) according to the associated risk
(b) To prioritize the compounds studied according to their relative contribution to the total risk
(c) To compare the two risk-assessment methods tested

[7]Studio Delta srl, SANTA CROCE SULL'ARNO (PI), Italy
Assessment of biogas emission from landfills is a relevant issue, both for environmental and economic reasons. In fact methane, a greenhouse gas, is one of the main component of biogas released in the atmosphere from landfills; moreover unexploited methane represents a loss of income for landfill power plants.
In Italy no national/local specific technical rules are in force for landfill gas emission assessment so the procedure recommended by the English Environmental Agency (EA) is commonly applied. This procedure is based on the integration of punctual flux emission measurements from the surface of the landfill.
In this work we propose an alternative method of landfill biogas emission measurement, based on the hypothesis that emitted biogas in stable atmospheric condition (constant wind with velocity lower then a fixed threshold) pertains to an emissive gas plume. The plume may be intercepted by a regular mesh of points located downwind of the landfill, where methane concentration is measured. Afterwards, atmospheric dispersion modelling allow us to estimate the methane emission from the landfill. In order to fulfil the above objective, we handled the following main steps:
a) Identification and set up of methods for measuring biogas concentration;
b) Calculation of total emission by modelling acquired data;
c) Comparison among results obtained applying different measurement methods.
We repeatedly (summer and winter seasons) applied the proposed methods to a set of municipal solid waste (MSW) landfills, either in activity or closed. We estimated methane concentration by means of the Tuneable Diode Laser technique adopted in the USA by the Environmental Protection Agency (EPA), which allowed us to obtain time-series of path-integrated concentration measurements within horizontal and vertical planes located above the landfill surface. We also performed direct sampling of the emissive plume by using a set of bags and remotely controlled air sampler devices, arranged to identify a vertical surface downwind of the landfill. We then measured methane concentration within the bags with a FTIR multigas analyzer.
In order to assess total methane emission, we processed the data obtained by the two above measurement methods by using a numerical code implementing an atmospheric dispersion model. We finally compared these outputs with total emission estimated by applying the EA recommendations as well as with emission estimated by using the BIO5 stechiometric numerical model.

## SS05 - LCA network: comparison of experiences

**SETAC Networking for Global LCA Science and Practice**
BW Vigon
SETAC, PENSACOLA, United States of America
For more than 20 years the Society of Environmental Toxicology and Chemistry (SETAC) has supported the global development and helped advance the scientific underpinnings of LCA. This support occurs through a variety of internal and external networking activities. Among these efforts are internal ones to SETAC where Advisory Groups on LCA at the European and North American levels provide a forum for discussion of critical issues and connection to external activities, such as the UNEP-SETAC Life Cycle Initiative. SETAC provides a scientific component to the Initiative, which it co-founded, and acts as an ISO TC 207 liaison on LCA work items. Recently, the Advisory Group network has been expanded to a global level.
Additionally, on the external side, SETAC has fostered networking globally via strong LCA programs at annual meetings, publication of scientific journal articles and books on LCA, and hosting/organizing of workshops on LCA topics. Four intensive, week-long workshops with global participation, employing a format and process developed by SETAC, have been held to advance the science of LCA. Most recently, one such workshop was held in Japan, under the auspices of the Life Cycle Initiative, to develop guidance principles on LCA datasets and databases. Other networking occurs through international programs, such as the Strategic Approach to International Chemicals Management (SAICM) and the UNEP Mercury Partnership.
This presentation will highlight SETAC's networking efforts on behalf of global LCA science with particular attention paid to the recent Pellston workshop and its forthcoming publication.

## SS06 - Emerging exposure science for developing chemical regulatory policy: REACh, biocides, TSCA reform

**SS06A-1**
**A Crosswalk of the Exposure Science Requirements of REACH, TSCA, CEPA and Biocides Legislation**
E Dederick
ICF International, FAIRFAX, United States of America
Thousands of legacy chemicals that have not undergone human and environmental risk assessments exist internationally. Under the United Nations Environment Programme (UNEP) Strategic Approach to International Chemicals Management, legislative bodies worldwide have committed to managing chemical production so that adverse impacts on the environment and human health are minimized. Multiple legislations exist to address domestic or regional chemical management programs, and these statutes also support UNEP objectives. While the objectives of these statutes are comparable, the specific scientific requirements for exposure and risk assessment differ. In order to comply with multiple legislations, scientists and decision makers must understand the differing requirements. There are thousands of pages of guidance to describe the legislative mandates, but navigating the guidance documents is an overwhelming task. The goal of this presentation is to provide an overview of the exposure science requirements of several international legislations, and in so doing to provide context for the regulatory panel discussion and the technical presentations in the Special Session on "Emerging Exposure Science For Developing Chemical Regulatory Policy." This presentation will focus on the scientific requirements of the following legislations: the EU Registration, Evaluation, Authorisation, and Restriction of Chemicals (REACH) legislation, the US Toxic Substances Control Act (TSCA), the Canadian Environmental Protection Act 1999 (CEPA 1999), and the EU Biocidal Product Directive (BPD), as well as similar biocidal legislation in North America.

**SS06A-2**
**Canada's Experience from Assessment of High Priorities under its Chemicals Management Plan**
CA Norman
Health Canada, OTTAWA, Canada
Assessing risk as part of Canada's global commitment to address legacy chemicals by 2020 is implemented through the Chemicals Management Plan. In 2006, Canada categorized approximately 23,000 existing commercial substances through a priority-setting exercise using available data, QSAR modelling, and simple tools that ranked substances based on a number of parameters including their potential for human exposure and persistence and bioaccumulation potential. Since 2007, Health Canada and Environment Canada have addressed the highest priorities from this exercise by jointly conducting screening assessments on approximately 200 substances as part of its 'Challenge' initiative. Experiences from this exercise and opportunities for increased collaboration moving forward will be the focus of the presentation.

**SS06A-3**
**Panel Discussion on Key Exposure Science Needs - A Regulatory Perspective**
A Ahrens[1], C Fehrenbacher[2], D Gutzman[3], T Leighton[2], L Van der wal[4]
[1]European Chemicals Agency, HELSINKI, Finland
[2]US Environmental Protection Agency, WASHINGTON DC, United States of America
[3]Environment Canada, GATINEAU, Canada
[4]European Commission Joint Research Centre, ISPRA, Italy
Exposure science is a key element in regulatory decision-making. In an interactive panel format, European and North American regulators will share their views on key exposure science needs for human and environmental exposure characterization moving forward within their legislative mandates. Panel members will discuss barriers to addressing these needs, as well as opportunities moving forward. The focus of the discussion will be on exposure science needs related to the following broad themes: access to structured and harmonized supply chain Information; exposure-based priority setting and screening; advancing predictive approaches; data generation and synthesis; informing risk management; and beyond a chemical-by-chemical approach.

**SS06B-1**
**Precision versus practicality; the derivation, construction and experience of the ECETOC TRA human exposure tools**
CD Money
ExxonMobil, DIEGEM, Belgium
The ECETOC Targeted Risk Assessment (TRA) model was originally launched in 2003 and a revised version of the TRA was made available in 2009. The TRA facilitates tier-1 risk assessments and allows discriminating between straightforward assessments, which can be successfully resolved by applying the TRA, and those assessments which need a more involved approach. In addition, the TRA produces an output which lends itself to standardized communication. With

these features, the TRA addresses the basic REACH needs for generating safety assessments for all dangerous substances and for communicating the assessment results in the supply chain. It is this improved version that has been endorsed within the REACH Technical Guidance for human health exposure assessment and Exposure Scenario development. The TRA has been applied in the vast majority of the 3400 Phase 1 (2010) REACH substance registrations where exposure assessments were required. As a consequence, ECETOC has been actively soliciting feedback from users of the TRA in order to better understand where improvement opportunities exist (whether for workers, consumers or the environment). No fundamental issues with the core structure of the TRA have been reported. But it is clear that further improvements can be implemented to extend the domain of the tool; the accuracy of exposure predictions; and its overall utility when viewed in the context of its workflows and industry IT platforms. It is also apparent that a significant minority of users have failed to follow some of the key recommendations for its reliable application. This highlights the importance of understanding, defining and refining applicability domains in order that tools such as the TRA can continue to be reliably and usefully applied in the process of chemicals risk assessment.

**SS06B-2**

**Aggregate consumer exposure assessment**

N von Goetz
ETH Zurich, ZURICH, Switzerland

Many chemicals that are being used in consumer products are contained in tiny amounts in the respective product. Exposure to the substance from one single product may therefore be insignificant from a risk perspective, while exposure to the same substance from different products can be high enough to pose a risk. Examples are important ingredients of personal care products (PCPs) like stabilizers, preservatives, and UV-filters. These are contained in different PCPs and cosmetics that are used at the same time. Also some high production volume substances like Bisphenol A (BPA) and the flame retardant polybrominated diphenylethers (PBDEs) are found in a large number of products that a consumer comes in close contact with. Examples are epoxy resins in food cans that release BPA into food and PBDE-doped upholstery, electronic equipment, carpets etc. Consequently, in order to obtain an estimate for the overall exposure many single-source exposures have to be added up. The technical term for this overall exposure is the total exposure, which is used when all sources that are currently known are taken into account in the assessment. If only one sector of products is accounted for, the technical term aggregate exposure is used for the sum of single-source exposure.

The main difficulties in assessing these aggregate (or total) exposures are the lack of data on substance sources (e.g. amount of substance included in a product) and the lack of data on consumer use of substances, and here mainly co-use data.

In order to illustrate the challenges of aggregate exposure assessment the key parameters in three exemplary studies on Bisphenol A, Nanoparticles and PBDEs are discussed. As key parameters those parameters were identified that introduce the largest known uncertainty: For Bisphenol A the intake of canned food contributes most to uncertainty, whereas for nanoparticles the lack of co-use data is critical for the assessment. For PBDEs the largest uncertainty is connected to PBDE concentrations in dust and dust intake rates.

Approximations for uncertain or lacking data will be discussed along with the consequences of their use.

**SS06B-3**

**Incorporating Population-Specific Diets and Activity Profiles into Aggregate and Cumulative Exposure Assessments: A Review of Capabilities and Shortcomings**

CF Chaisson, CA Franklin
The LifeLine Group, ANNANDALE, United States of America

Starting with a review of the existing and emerging regulatory mandates of Europe and North America, we will present a listing of needed exposure assessment capabilities juxtaposed to capabilities offered by contemporary models and possible sources of information needed for population-specific exposure assessment. Models designed to utilize atypical formats of dietary and activity profile information will be highlighted to illustrate the capacity and relevance to aggregated risk assessment for consumer products using population-specific information. The LifeLine Dietary Record Generator and Activity Profile Generator and will be used to illustrate the structured approach and mathematical processes involved. While these kinds of models provide significant advantages to capture valuable exposure-related information for any population group, regulators and assessors must understand their inherent limitations and know how to ground-truth their predictions. Accurate exposure assessments also require relevance to changes in product use profiles as the seasons change, or in variation across populations because of economics, ethnic traditions, gender or age preferences and because of health related influences on diet and activity and product use. We will demonstrate approaches for amending older existing national survey data using contemporary market information about the products used by the populations in those surveys. Such approaches combine multiple sources of information to extend the shelf life of expensive databases and improve the accuracy and relevance of resulting exposure assessments. Examples will show how information was collected from local and publicly available sources, and incorporated into the exposure assessment. Issues emerge about data quality, qualifications of "experts"at the local level, anticipating product competition and associative use of multiple products.

**SS06B-4**

**Setting the scene: Is mixtures risk assessment necessary and feasible?**

A Kortenkamp
University of London, LONDON, United Kingdom

There is currently considerable interest in considering whether chemicals risk assessment with its traditional focus on chemical-by-chemical evaluations should be expanded to take account of mixture effects. During the last 10 years, research on mixtures has made significant advances, especially in human and mammalian toxicology. This presentation will give a summary of the scientific state of the art of mixture toxicology and will reflect on issues of regulatory relevance for both environmental and human risk assessment. The traditional focus on chemical-by-chemical assessments could be justified, if in typically encountered exposure scenarios only one chemical was toxic, or if the joint action of several chemicals was typically not larger than the most toxic agent in the mixture. However, evidence from experimental studies shows that this is not normally the case. Similarly, there would be no need to take account of mixture effects if there was always sufficient protection when all chemicals are present below their threshold doses. Examples from the literature will be presented which show that combination effects can occur at low doses. This will be followed by a discussion of the general principles behind such phenomena. Experimental mixture studies in ecotoxicology and human toxicology demonstrate that the concepts of dose addition and independent action provide good approximations of observed combination effects. Significant deviations from expected additive effects have only rarely been observed, and when they occurred, the deviations were not large. This argues for using these concepts in mixtures risk assessment. Case studies where mixtures risk assessment has been used in practice will be critically discussed.

The talk will end by highlighting two areas important for better mixtures risk assessment: Firstly, scientifically sound criteria for the grouping of chemicals for cumulative risk assessment are needed. The discussion currently focuses on using toxicological similarity as a grouping criterion, but this may not be decisive in all cases.

Secondly, mixtures risk assessment will have to rely on sound information about cumulative exposures, but our information about combined exposures is fragmentary at best. **Acknowledgement** - The authors thank the Europesn Commission for financial support (study contract 070307/2007/485103/ETU/D.1)

**SS06C-1**

**Challenges ahead in mixtures and cumulative environmental assessments**

TP Traas, DTHM Sijm, CWM Bodar
RIVM, BILTHOVEN, The Netherlands

The debate on how to deal with mixtures in risk assessment has been refuelled. This presentation will give an overview of the problems, methods and way forward for environmental risk assessment of mixtures in some current legislative frameworks.

Several studies with mixtures of chemicals with similar and dissimilar modes of action have confirmed that concentration addition (CA) is a conservative estimator of the toxicological effect of mixtures. Due to this - in most cases relatively modest -overprediction, CA be used in risk assessment as the default approach.

Several approaches can be used to express the overall toxicity of the mixture; as toxic units, TEQ values as the sum of risk quotients, or as the fraction of species in the ecosystem that is potentially affected due to the mixture.

Exposure to mixtures of substances presents classical challenges but quite different issues may need to be tackled. Is it an interest in exposure to toxicants not known a priori, or limited to those toxicants known from monitoring or a specific class or category of chemicals? Both monitoring studies and modelling studies have shown that generally, toxicity of mixtures in the field is dominated by a fairly limited number of substances. Even though such findings are encourageing, it is still necessary to characterise these main toxic components by chemical analysis, possibly in combination with smart screening tools for specific modes of action (TIE).

It is difficult to adapt risk assessment procedures in current EU legislation in such a way that one approach fits all problems. As an example, a recent study on mixture toxicity of Dutch surface waters has shown that a few individual substances dominate toxicity at many sites. In such cases, better control and stricter quality objectives can dramatically improve overall water quality.

More specifically, risks of mixtures of specific substances (e.g. EDC) can be of interest. In a specific project on estrogenic activity of surface waters in the Netherlands (LOES a few specific hot spots were found but some estrogenic activity could generally be detected at most sampling sites. In this case, targeted measures can be taken at hot spots, reduce the load of e.g. synthetic hormones or adapt water treatment schemes.

Both REACH and the Water Framework Directive offer possibilities to regulate individual chemicals or groups of chemicals that have been identified in mixture toxicity studies.

**SS06C-2**

**Models in environmental chemistry education, science and decision-making**

M MacLeod[1], M Scheringer[2], K Hungerbuehler[2], TE McKone[3]
[1]Stockholm University, STOCKHOLM, Sweden
[2]Swiss Federal Institute of Technology, ZURICH, Switzerland
[3]Lawrence Berkeley National Laboratory & University of California Berkeley, BERKELEY, United States of America

The last decades have seen a revolution in the development and application of mathematical models as tools for studying environmental and human health problems, and for developing regulatory strategies to address those problems. Models are now indispensible in the daily work of many educators, scientists and decision-makers in the field of environmental chemistry. When faced with a new problem, scientists and policy-makers can often choose from a variety of models with different levels of detail, and differing levels of fidelity to the real system of interest, or they may contemplate developing a new model to address their particular challenge. In this presentation we examine the motivations for developing and applying quantitative models to describe environmental systems, and confront the inherent limitations of such models. Based on this general discussion, we identity the roles that models play in modern education, science and decision-making in environmental chemistry and exposure assessment. Some advantageous uses of models in these applications will be illustrated with case studies from our own experience.

**SS06C-3**

**Regulatory Environmental Exposure Assessments: General Approaches and Use of Market Research Data to Improve Emission Estimates**

PJ Mason[1], GO Hughes[1], OR Price[2], TJ Kedwards[3]
[1]Cambridge Environmental Assessments, CAMBRIDGE, United Kingdom
[2]Unilever - Safety & Environmental Assurance Centre, COLWORTH, United Kingdom
[3]S C Johnson, CAMBERLEY, SURREY, United Kingdom

This presentation provides an introduction to the methodologies used for environmental exposure estimation as part of the regulatory risk assessment process performed for biocides (under 98/8/EEC) and general chemicals (under REACH). The first-tier emission estimation frameworks used for general chemicals and biocides necessarily include conservative default assumptions. In cases where more specific information is available, it may be justified to refine some of these assumptions. An example is the "10 % rule"which is typically applied to tonnage-based assessments for wide dispersive/consumer uses of substances. By linking population density and country-specific usage statistics it is possible to investigate the validity of this assumption. The results of such an analysis performed for home care products suggest that a refined figure of 4% of EU tonnage used in a hypothetical region (200 [GREEKX] 200 km) region can be justified. A similar analysis performed for consumer uses of insecticide products also indicates that the "10% rule"represents a worst-case for a number of product categories. Thus, it is demonstrated that considerable scope exists for refining emission estimates for some chemical uses.

**SS06D-1**

**Linkages between Human Health and Environmental Assessment**

F Mitchell, P Delorme
Health Canada, OTTAWA, Canada

This presentation will explore similarities in the challenges inherent to human health and environmental exposure and risk assessments, and how best practices can be applied across the disciplines to increase confidence. All exposure assessments share the same basic goal, to estimate whether a given receptor can be exposed at a high enough dose, for a long enough time, to potentially cause adverse effects. There are, however, major differences that derive in part from differences in risk assessment objectives. Human health assessments aim to protect the individual and usually consider a range of routes and durations of exposure, while environmental assessments generally aim to protect at population, habitat or ecosystem levels of organization and have historically been largely focussed on acute toxicity. The high diversity of ecological assessments, and the wider range of protection goals, means that environmental assessment frameworks are generally less standardised, and in some cases less developed, than those for human health. While both fields are developing approaches to better consider aggregate effects across exposure routes, and cumulative effects across chemical classes, this area is currently more advanced for human risk assessments. Confidence in any assessment depends on the quality of the data available and the scientific strength of the assumptions that underlie the assessment model. Reliance on surrogate data and broad extrapolation of data results in the need to address not only the variability inherent to a situation of interest, but uncertainties in how well the measured or monitored data simulates the "real"situation. Adequate characterisation of variability and uncertainty, and the biases they may introduce, is critical. This presentation will illustrate these challenges, using examples drawn from the assessment of human and environmental exposure to pest control products. The relative utility of simple deterministic and more complex stochastic models will be explored, along with opportunities to better integrate and harmonise research and monitoring resources and model development and validation across the disciplines.

**SS06D-2**

**Thresholds of Toxicological Concern**

RJ Safford
Unilever, SHARNBROOK, United Kingdom

Conceived over 40 years ago as a "common sense"approach, the Threshold of Toxicological Concern (TTC) is a useful concept that is becoming of increasing interest as an addition to the arsenal of tools used for characterising the toxicological and environmental risks from low level exposure to chemicals. Initially used by the USA FDA for low levels of indirect additives in foods (packaging migrants), the TTC has subsequently found uses in safety evaluation of flavours, genotoxic contaminants in drug products and contaminants in foods. In these cases the TTC obviates the need for toxicological testing of chemicals where human exposure via the oral route is low. A more recent proposal has been made to extend its use to human exposure via the dermal route (i.e. from low levels of ingredients in cosmetic and personal care products) and from the inhalation route. For these latter two exposure routes, both local effects and systemic effects are taken into consideration. In all cases, threshold levels have been established by using a probabilistic analysis of existing toxicological data, from which it can be concluded that the risk of adverse effects from human exposure to levels of an untested chemical at or below the TTC is minimal. Further proposals have been made to extend the use of the TTC in ensuring environmental protection. These include use for organic chemicals in fresh water systems based on mode of action (Exposure Thresholds of No Concern, or ETNC), and an examination of the feasibility of using a TTC for endocrine active substances in the aquatic environment. Use of the TTC principle may preclude the need for additional toxicity or environmental testing in cases where exposure is sufficiently low. The TTC concept benefits consumers, industry, and regulators, by avoiding unnecessary extensive testing and safety evaluations, thus allowing limited resources of time, animal use, cost, and expertise to be devoted to the testing and evaluation of those substances with greater potential to pose risks to human health or the environment.

**SS06D-3**

**Criteria for Exposure Based Waiving under REACH**

TG Vermeire[1], Y Bruinen de Bruin[1], A Den Hollander[2], J Van Engelen[1], H Marquart[3], T Meijster[3]
[1]RIVM, BILTHOVEN, The Netherlands
[2]Radboud University, NIJMEGEN, The Netherlands
[3]TNO Quality of Life, ZEIST, The Netherlands

Within the REACH framework, but also within OECD, there is understanding that for reasons of animal welfare, costs and logistics, it is important to limit the number of tests to be conducted. Exposure based waiving (EBW) is a potentially important element in testing strategies. This presentation reflects on criteria for EBW as foreseen in the REACH regulation and proposes a strategy for its implementation. The emphasis will be on the evaluation of exposure assessment models with regard to their suitability for EBW-decisions under REACH. We have developed such decision trees for environmental and human exposure. Human exposure includes occupational exposure, consumer exposure and human exposure via the environment.

The principle behind any EBW is that there are situations when human or environmental exposures are so low or infrequent that there is a very low probability that the acquisition of additional effects information may lead to an improvement in the ability to manage risk. EBW therefore is risk based and needs thorough knowledge on exposure as well as on effects criteria. Both elements are discussed: exposure models are analyzed and the uncertainty in their predictions discussed as well as no-effect criteria. The justification for EBW can be based on qualitative or quantitative argumentations, or on a combination of both. Quantitative justification for EBW needs an assessment proving that exposure is below a 'No-Further-Action Level' (NFAL) such as a PNEC (Predicted No-Effect Concentration), DNEL (Derived No-Effect Level), DMEL (Derived Minimal-Effect Level) or TTC (Threshold of Toxicological Concern). Examples are provided to illustrated the EBW-methods proposed.

**SS06E-1**

**Linking sources with outcomes: The science of stressors and receptors**

TE Mckone
University of California, BERKELEY CA, United States of America

Among the issues that create demand for exposure science are (a) the need for identifying and classifying exposures in health surveillance studies, (b) the need in fields such as life-cycle assessment and green chemistry to anticipate exposures from new and existing chemicals in order rank and evaluate products and chemicals, (c) addressing climate change and its impacts on humans and ecosystems, (d) regulating new and existing substances, and (e) the need of industry to provide sustainable products and services. This presentation addresses the factors that create a growing demand for exposure information, the tools we have to address these demands, and the opportunities for expanding these tools and for building new science and new technologies to address the demands for exposure information. To achieve this I will begin with defining and illustrating the core elements of an exposure science "' stressors, receptors, outcomes, and the spatial/temporal contact between stressors and targets the results in outcomes. We will then identify the nature and extent of the demands for exposure science in a number of research efforts. We will consider how activities such as environmental chemistry, biomonitoring, pharmacokinetics, activity tracking, and modeling are addressing these demands. Finally we will consider how these efforts can be expanded and better integrated to improve the relevance and reliability of exposure science.

**SS06E-2**

**From globalization to molecular biology: Extending exposure science across all levels of biological organization for sustainable environmental health policy**

EA Cohen Hubal
US Environmental Protection Agency, RESEARCH TRIANGLE PARK, NC, United States of America

The start of the 21st Century has seen increasing trends toward globalization and continuing advances in molecular biology. These two seemingly disparate drivers provide the imperative for extending consideration of exposure across multiple scales to facilitate systems based analysis for holistic environmental and public health policy design. As understanding of how to assess and mitigate frank impacts from simple exposures to known pollutants improves, scientists are moving toward a broad view of environment, holistic consideration of human-environment interaction, and characterization of biological complexity to understand influence of these on human health. Operationalizing sustainability concepts to address chemicals management will be facilitated by application of approaches such as those used by ecologists to study resilience of linked social-ecological systems. Consideration of the amount of change a cell, organism, community, or social-ecological system can undergo while still retaining important controls on function and structure could provide a holistic approach for assessing cumulative risks, particularly to vulnerable groups. More globally, application of this type of systems-based approach has the potential to improve our ability to predict and minimize unintended consequences of environmental health decisions.

**SS06E-3**

**Exposure Biology and the Exposome: a Health-Based Paradigm for Exposure Science**

SM Rappaport
University of California, Berkeley, BERKELEY, CALIFORNIA, United States of America

Exposure biology is a term that encompasses connections between environmental factors and their interactions with genetic and epigenetic states. Early exposure scientists applied principles of exposure biology in occupational studies to advance our understanding of the toxicodynamics of fibrogenic dusts, respiratory irritants, heavy metals, and some systemic toxicants such as benzene. With the birth of the U.S. EPA, exposure scientists largely abandoned exposure biology in favor of methods to predict air and water concentrations of regulatory pollutants. Such emphasis on air and water pollutants ignores toxic chemicals, arising from the diet and endogenous processes such as inflammation, which are probably much more important contributors to heart disease, diabetes and cancer. Thus, by abandoning exposure biology, exposure science has become only marginally relevant to our understanding of the etiologies of modern chronic diseases. The concept of the exposome, representing all exposures received by a person from both external and internal sources, motivates a holistic view of biologically active chemicals in an individual's internal chemical environment. To characterize the exposome it makes sense to use a top-down approach based upon biomonitoring rather than a bottom-up approach limited to external inputs from air, water and food. Because the exposome varies in space and time, initial investigations could use archived blood and 'omics' techniques to measure important classes of toxic chemicals - including reactive electrophiles, metals, metabolic products, hormone-like substances, and persistent organic compounds - in prospective conort studies. These twin concepts of exposure biology and the exposome offer health scientists an avenue for conducting environment-wide association studies (EWAS) to complement genome-wide association studies (GWAS) that are now commonplace. Indeed, designs which interleaf EWAS with GWAS, can pinpoint key exposures responsible for chronic diseases as well as important gene-environment interactions. Such investigations would also generate vast data resources that can be exploited by systems biologists to enrich our understanding of disease processes and mechanisms. Exposure scientists can play a key role in this exciting research if they adopt a health-based paradigm which embraces exposure biology and the exposome.

**SS06F-1**

**Using pharmacokinetic approaches based on animal and human datasets to track and allocate cumulative exposures and aggregate health impacts**

HJ Clewell
The Hamner Institutes for Health Sciences, RESEARCH TRIANGLE PARK, United States of America

Multi-chemical exposure is the rule rather than an exception in both the general and the occupational environment. Simultaneous or sequential exposure to multiple chemicals may cause alterations in the pharmacokinetics (PK) and/or pharmacodynamics (PD) of the individual chemicals, resulting in a change in the toxicity predicted based on the summation of the effects of the components. PK interactions occur as a result of one chemical altering the absorption, metabolism, distribution, and/or excretion of other chemical(s). Such interactions often result in a modification of the internal or target dose of one component of a mixture by another component. In such cases, conducting quantitative risk assessment for chemicals present as a mixture is difficult. The uncertainties that arise from changes in the PK of the components can be addressed by developing physiologically based descriptions of the disposition of chemical mixtures that can be used for dose, route, and interspecies extrapolations of the target tissue concentration of the toxic moieties. Further, biologically based models for mechanisms of action and tissue response can be developed to integrate the PD interactions of the chemicals into the predictive modeling framework. The parameters for the PK and PD models can be determined from in vitro experiments using human cells or tissues. Such a quantitative mechanistic approach to the study of chemical interactions is imperative to achieve the ultimate goal of assessing the health risks associated with human exposure to complex chemical mixtures.

**SS06F-2**

**Mobility-based exposure assessment**

JD Marshall
University of Minnesota, MINNEAPOLIS, United States of America

People's daily mobility - for activities such as work, shopping, and recreation - brings them in contact with air pollution concentrations that may differ from the concentration at their home location. However, many population exposure assessments are based on census data, which are implicitly home-based.

This presentation compares existing and potential future methods for accounting for mobility in exposure assessment, and also will discuss when mobility is, or is not, an important component of exposure assessment. These issues are intimately connected with the degree of temporal and spatial variabilty in pollutant concentrations (and people's locations).

**SS06F-3**

**Using exposure models to identify data gaps and develop knowledge infrastructure**

A Arnot
University of Toronto Scarborough, SCARBOROUGH, Canada

In recent decades regulations and methods have been developed to evaluate tens of thousands of chemicals; however, there are few measured data available for the legislated assessments. In this context, conceptual models are needed for screening and priority setting and mathematical models (mass balance and QSARs) are required to generate data. This presentation illustrates how mass balance exposure models can be used to screen and prioritize chemicals for more comprehensive assessments. The integrated, "holistic"framework exploits sensitivity and uncertainty analysis to identify and prioritize data gaps and to build knowledge infrastrucure (databases and QSARs). Mass balance exposure model hypotheses (i.e., predicted concentrations) can be evaluated ("ground truthed") with monitoring data following the incremental stages from emisisons to concentrations in the environment, to food sources and to humans. During this evolutionary process (model development, application, evaluation, refinement) there is a need to balance data availablility (uncertainty) and regulatory needs (timeframes). Various exposure and risk assessment frameworks can be established with different objectives and levels of model complexity. The general approach outlined here can be used to identify data gaps and build databases and predictive tools to reduce uncertainty in exposure and risk assessments and regulatory decision-making.

**Effects of warming and cadmium on the feeding behaviour and growth of the aquatic invertebrate shredder Limnephilus sp.**

DM Batista[1], C Pascoal[2], F Cássio[2]
[1]University of Minho, BRAGA, Portugal
[2]Centre of Molecular and Environmental Biology (CBMA), BRAGA, Portugal

Metal contamination is still an environmental problem and can affect several species of invertebrates at environmentally realistic concentrations. Invertebrate shredders play an important role in plant litter breakdown, since they participate in the fragmentation of plant material and decomposition of coarse particulate organic matter. The Intergovernmental Panel on Climate Change predicts an increase in water temperature that may affect invertebrates, causing faster growth rates, shorter developmental time and smaller size at maturity and reduce the ability of invertebrate survival on poor nutrient diets. It is probable that the combined effect of metals and increased water temperature may have strong impacts on the processes in which invertebrate shredders are involved, further compromising the functioning of freshwater ecosystems. Therefore, we tested how leaf consumption by invertebrate shredders and their growth are affected by cadmium and whether increasing temperature modulates this relationship. A common species of invertebrate shredder was collected from an unpolluted stream and acclimated to the laboratory. In one experiment, the animals were allowed to feed on alder leaves, while exposed to increased Cd concentrations (3 levels, ≤ 10 mg/L) and to a temperature typically found in streams in autumn (15ºC) and to 21ºC to simulate a warming scenario. In another experiment, the animals were kept under starvation for 4 days while exposed to cadmium (10 levels, ≤ 35 mg/L) and then were released from the stressor and allowed to feed on alder leaves. Cadmium content on leaves and animals was analyzed by inductively coupled plasma-atomic emission spectrometry. The exposure to Cd decreased the consumption rate by shredders but not its growth rate. We also observed an increased invertebrate feeding activity at higher temperature. Cadmium accumulated more in the leaves than in the animals. In conclusion, results indicate that the increase in Cd concentration and an increase in temperature of 6ºC affected the feeding behavior and growth performance of the invertebrate shredders Limnephilus sp.. This may compromise at longer times the survival of sensitive shredder populations with direct impacts to plant litter decomposition and nutrient cycling in freshwater ecosystems.

**CS01A-2**

**The effect of temperature on the toxicity of cadmium towards Caenorhabditis elegans**

NJ Nørhave[1], N Cedergreen[1], HL Hooper[2], DJ Spurgeon[2], C Svendsen[2]
[1]University of Copenhagen, FREDERIKSBERG, Denmark
[2]Centre for Ecology and Hydrology, WALLINGFORD, United Kingdom

Temperature has in the past few decades been shown to be an important factor in ecotoxicology. As both biological and chemical reactions are determined by the ambient temperature it follows that many processes involved in the toxicological profile of a chemical, such as biological degradation rates, growth rates and general metabolic rates, as well as abiotic degradation, absorption and diffusion rates, all are temperature dependant. It is therefore expected that the toxicity of a compound will also change with temperature. In this study we determined the effect of different ambient temperatures on the reproduction, lifespan and intrinsic population growth rate of nematode *Caenorhabditis elegans* exposed to cadmium, in an agar based test system. The total reproduction and lifespans of *C. elegans* were very similar for all cadmium treatments, so these endpoints on their own would suggest that there was no significant difference between the toxic effects of the concentrations used. Fertility, however, expressed as "Time to first egg", was a most sensitive endpoint. Hence, when all endpoints were combined in a three component population growth model the effect of the individual cadmium doses showed that the high doses have detrimental effects at high temperatures, while population growth can still take place at the low temperatures. This demonstrates the importance of evaluating the toxic effect of chemicals on population levels rather than on single endpoints determined from individuals.

**CS01A-3**

**Low temperatures enhance the chronic toxicity of Cd and Cu through different mechanisms**

N Cedergreen[1], JK Nielsen[1], HKL Johansson[1], H Marcussen[1], PE Holm[1], C Svendsen[2], D Spurgeon[2]
[1]University of Copenhagen, FREDERIKSBERG, Denmark
[2]Centre for Ecology and Hydrology, WALLINGFORD, United Kingdom

The effect of cadmium and copper on the reproduction of the enchytraeid worm Enchytraeus crypticus was investigated at temperatures representative of different climatic region of temperate areas. The aim of this study was to investigate the influence of temperature on metal toxicity. The effect of both metals was investigated at six different temperatures (11°C, 13°C, 15°C, 18°C, 21°C and 25°C). As differences in metabolic rate at different temperatures would likely result in different uptake and excretion kinetics of the metals, exposure durations were varied and experiments terminated when there was 100-200 juveniles in the control containers. EC10 and EC50 values for effects on reproduction were obtained. The EC50 values for both cadmium and copper toxicity towards reproduction declined in a linear pattern with temperature. Going from 25°C to 11°C this resulted in a two-fold decrease of EC50 for Cd and a three-fold decrease for the EC50 of Cu. Internal concentrations of Cd and Cu in worms at 11, 18 and 25 °C were measured over time. These results showed that tissue-Cd accumulated faster and to higher levels at 25°C compared to 18 and 11°C. However, in the Cu treated worms, tissue concentrations were lower at high temperatures. This indicates that the mechanisms behind the temperature induced changes in toxicity of the two metals are different. Possible causes behind these differences will be discussed.

**CS01A-4**

**Ecotoxicity under impact of climate change: Temperature modulates toxicity of the fungicide pyrimethanil**

A Seeland[1], R Müller[2], J Oehlmann[1]
[1]Goethe University, FRANKFURT, Germany
[2]LOEWE Biodiversity and Climate Research Center, FRANKFURT, Germany

Mean temperatures will increase by 2.5°C in spring and summer till 2080 in Hesse (Germany). Additional climate change effects will result in generally warmer springs and moister summers. These altered climatic conditions may lead to higher agricultural consumption of pesticides, particularly of fungicides. The run-off of these pesticides into nearby water bodies will become enforced by more frequent extreme rain events. The aim of the study was to investigate if the ecotoxicological impact of the fungicide pyrimethanil on aquatic key species is altered under future temperature scenarios.

We examined the model substance pyrimethanil (fungicide) in standard ecotoxicological test designs with aquatic primary producers and invertebrates. Among 5 tested model species, *Daphnia magna* was the most sensitive organism. In the following we tested the response of *D. magna* to low doses of pyrimethanil in a multigenerational experiment simulating dynamic temperature regimes in Hesse´s waters today and in future ("cold year today", "warm year today", "warm year 2050 - 2080").

Most juveniles were detected under warm temperature conditions expected for 2050-2080. Surprisingly offspring was not positively correlated with rising temperature in "warm year"simulations. Instead we observed reproductive minima and maxima over experimental time course, just offspring under "cold year"conditions followed temperature gradient. Additional effects of low dose of pyrimethanil were often masked by temperature and only observed in generations being in an optimal reproductive state.

With increasing temperatures in the future the effects of the pesticide may occur at lower concentrations than today. Furthermore the result of an enhanced reproduction rate in the future temperature scenario indicates increased zooplankton abundances due to warmer springs. In consequence, this may also affect the phytoplankton as a result of enhanced feeding activity of the zooplankton. Finally the timing and duration of clear water phases in lentic systems may be altered.

Multigeneration experiments under predicted climate scenarios are a useful tool to assess the impact of currently used pesticides under future climate change conditions. The results of the study indicate that xenobiotics may have a stronger effect on the biocoenotic structure and finally on the productivity of limnic ecosystems in the future with the expected temperature increase.

**CS01A-5**

**Combined effects of soil moisture and a fungicide on soil organisms - a study with Terrestrial Model Ecosystems -**

C Bandow[1], A Coors[2], B Förster[2], EL Ng[3], J Römbke[2], JP Sousa[3], J Oehlmann[4]
[1]BiK-F / ECT, FLÖRSHEIM, Germany
[2]ECT Oekotoxikologie GmbH, FLÖRSHEIM, Germany
[3]IMAR-CMA, University of Coimbra, COIMBRA, Portugal
[4]Goethe University Frankfurt/Main, FRANKFURT/MAIN, Germany

1. Introduction

The German Federal Environment Agency is expecting a decrease of summer precipitation of circa 16-19% in 2071-2100 and an increase by 10-20% in winter in comparison to the reference period of 1961-1990 for Hesse/Germany. The Intergovernmental Panel on Climate Change (IPCC) predicts substantial increase in the intensity of daily precipitation events in the Mediterranean region, while mean precipitation may decrease by 30-45%. Changes in precipitation may lead to changes in soil moisture content. When exposed to this climate-related stressor organisms may react differently towards chemicals (e.g. pesticides).

2. Materials and methods

Two studies were conducted. One took place in Portugal, the second in Germany. In both cases, the terrestrial model ecosystems (TMEs) consisted of intact, undisturbed soil cores. In Germany, the fungicide pyrimethanil was investigated at 11 concentration levels, each at three different moisture regimes in two replicates. In the Portuguese TME study the same endpoints were investigated, but with a Mediterranean soil and its community. The design differed from the German study, with only two fungicide concentration levels but four replicates per treatment. Two and eight weeks after application of the fungicide the sampling was conducted.

In this contribution, the effects of three moisture levels and different concentrations of pyrimethanil on the abundance and diversity of enchytraeids as well as the feeding activity of the soil organisms and their vertical distribution will be presented.

3. Results and discussion: Enchytraeids and feeding activity

Both study sites can therefore be considered as "rich"in enchytraeids. In Germany, the abundance of the enchytraeids was significanctly affected by the fungicide as well as by soil moisture. Feeding activity differed between the nominal moisture levels and showed an opposed effect in depth profile. At high moisture levels the feeding activity had its highest values in the top 4 cm, while in dry soil the activity is higher in deeper layers.

4. Conclusions

For the abundance of the enchytraeids no interaction between soil moisture and pyrimethanil could be detected. In contrast, feeding-activity, responded to the interaction of climate and chemical stressor, at least at nominal values. Further statistical evaluation of actual moisture contents, taxon-specific abundance and analytical measurements of the exposure concentrations are in progress.

**CS01A-6**

**Antioxidant defenses and oxidative damage in amphipods under multiple stressors**

E Gorokhova[1], M Löf[1], HP Halldórsson[2], U Tjärnlund[1], M Lindström[3], M Reutgard[1], T Elfwing[1], B Sundelin[1]
[1]Stockholm University, STOCKHOLM, Sweden
[2]University of Iceland, SANDGERÐI, Iceland
[3]3Tvärminne Zoological Station, University of Helsinki, HANGÖ, Finland

In estuarine systems, bottom hypoxia and increasing pollution load are the main stress factors causing alterations in benthic communities, yet little is known about their combined effects on estuarine organisms. We tested the individual and combined effects of exposure to hypoxia and to polluted sediment at environmentally realistic concentrations on the Baltic amphipod Monoporeia affinis using a suite of biomarkers.

In the first stage, amphipod responses to different combinations of oxygen levels (hypoxia vs. normoxia) and contaminant (polluted vs. unpolluted sediment) were determined using antioxidant enzyme activities (SOD, CAT, and GST), lipid peroxidation status (TBARS), protein carbonyl content (PCC), and DNA integrity (DNA-SB), and acetylcholinesterase (AChE) activity. There were significant increases in CAT and SOD activities and TBARS levels in response to both moderate hypoxia and contaminated sediment, while GST increased and AChE decreased in response to the contaminants only. Significant positive correlations were observed among the antioxidant enzymes and between the enzyme activities and TBARS concentration, suggesting a complex response to the oxidative stress. Furthermore, the negative effect of hypoxia on DNA integrity was significant; with frequency of DNA-SB increasing in animals exposed to hypoxia in contaminated sediment. Stepwise discriminant analysis allowed 75-100% correct discrimination of amphipods according to their treatment group; this grouping aids in stress assessment in field-sampled animals as well as understanding general patterns in the data that may guide future research.

In the second stage, we hypothesized that amphipods exposed to naturally occurring fluctuating hypoxia may develop adaptations to survive and recover upon reoxygenation, whereas exposure to contaminants would exacerbate oxidative stress in hypoxia-challenged animals and compromise the recovery. This hypothesis was tested using the most informative biomarkes identified in the first stage. The results support the hypothesized potential of xenobiotics to hamper ability of benthic animals to cope with changes in oxygen regime, such as fluctuating hypoxia and migrations from hypoxic to oxygenated environments. Thus, to predict the outcome of hypoxia effects in polluted coastal areas, it is crucial to understand the interactions between antioxidant responses to contaminants and hypoxia and physiological mechanisms causing and counteracting oxidative damage.

**CS01B-1**

**Interactions between depletion of ozone and climate change: a tale of two pollutants**

R Solomon

Centre for Toxicology, GUELPH, Canada

Although the Montreal protocol is working, climate change will influence the recovery of stratospheric ozone and also cause significant changes in the environment that will affect organisms as well as processes in the environment. Photochemically produced tropospheric ozone ($O_3$) is projected to increase over the next 20-40 years in certain regions of low and middle latitudes because of interactions of emissions, chemical processes, and climate change. If emissions of anthropogenic air pollutants from combustion of fossil fuels, burning of biomass, and agricultural activities continue to increase, concentrations of tropospheric $O_3$ will tend to increase. Numerical models suggest that annual deaths due to ground-level oxidants such as $O_3$ alone could reach 2 $x10^6$ in 2050, while the cost of crop damage is predicted to be of the order of US \$20$x10^9$ pa by 2030 with additional effects on non-crop plants. Decreases in precipitation and increasing temperatures due to climate change are likely to restrict plant growth and compromise the ability of plants to re-distribute resources for protection from UV radiation and other environmental factors - especially important in harsh environments. Consumption of plants by herbivores usually decreases under elevated UV-B radiation because of increased synthesis of compounds that absorb UV-radiation and also deter herbivores by acting as antifeedants. Over the coming decades, rising concentrations of $CO_2$ in the atmosphere and increased planting density may counteract this beneficial effect of UV-B radiation. Acidification of lakes and oceans is a major stress factor closely related to climate change and solar UV-B radiation. Increasing acidification of marine waters due to increased atmospheric concentrations of $CO_2$ decreases the rate of incorporation of carbonate in many marine organisms and makes them more vulnerable to solar UV-B radiation. Pre-industrialization, the concentration of $CO_2$ in the atmosphere was about 280 ppmv. This corresponded to an average pH in the oceans of about 8.2. The current level of 390 ppmv $CO_2$ has lowered the pH of oceanic waters by about 0.1 units. A further decrease in pH of 0.3 - 0.4 units is expected by the year 2100. Increased melting of ice sheets will reduce the concentration of colored organic matter in waters and allow increased penetration of UV radiation with resultant increased damage to aquatic organisms.

**CS01B-2**

**Are melting glaciers increasing exposure of Alpine wildlife to contaminants?**

E Elliott[1], F Guigeno[2], H Elliott[2], J Levac[2], P Shaw[1], M Wayland[1], DCG Muir[1]

[1]Environment Canada, DELTA, Canada

[2]University of Manitoba, WINNIPEG, Canada

Due to climate change, chemicals that accumulated in glaciers through evaporation from warm regions and subsequent condensation in cold regions are being released into alpine environments. To examine the role of glacial geography in determining contamination of wildlife in alpine ecosystems, we measured persistent organic pollutants and mercury in apex predators, ospreys (Pandion haliaetus) breeding in 16 watersheds in western Canada. Despite living in environments far from point sources of contamination, ospreys in Canadian alpine lakes had significant levels of DDT, PCBs, toxaphene and mercury. After accounting for proximate factors such as trophic level and lipid content, HCB, chlordane, mercury, PCBs decreased with watershed size and toxaphene, DDT, HCB and mercury decreased with watershed size divided by lake size. Ospreys feeding in large watersheds that drain into relatively small lakes had higher levels of contamination. Toxaphene, mercury, HCB, and DDT all decreased with the amount or proportion of glaciation while toxaphene and chlordane decreased with elevation. Thus, foraging ecology (trophic level) and geography explained significant portions of the large variation in osprey contaminant levels in western Canada, but the geographical variation was not consistent with the idea that the patterns in contaminants were determined by current long-range transport or glacial melt. Rather, we suggest that contaminants largely melt out during annual snow pack melt and bioaccumulate at lower elevation lakes, especially low elevation lakes with poor drainage. Our study highlights the importance of understanding how biological processes integrate physical patterns when studying the environmental chemistry of wildlife.

**CS01B-3**

**Surface water quality and climate change issues: impact of hydrology and temperature on total organic carbon and nitrate in small scale water services**

I Delpla[1], S Merel[2], E Baurès[1], AV Jung[3], F Petavy[3], M Clément[1], O Thomas[1]

[1]Environment and Health Research Laboratory, French School of Public Health, RENNES, France

[2]Department of Chemical and Environmental Engineering, University of Arizona, TUCSON, United States of America

[3]School of Environmental Engineering, BRUZ, France

The increase of mean temperature on Earth and its consequence on extreme meteorological events like floods and droughts have raised climate change issues to a major environmental and public health concern. These events induce very low or very high river flows that may impair the quality of surface water with some potential health impacts when used for drinking water production by small scale water services (SSWS). This study aims at assessing the impact of temperature and hydrology on surface water quality with particular emphasis on the amount of total organic carbon and nitrate. Data of 3 French rivers was gathered over a 26 year period, from 1983 to 2009. It appears that a rise of water temperature can be associated with a slight increase of total organic carbon concentration while the amount of nitrate becomes lower. Additionally, the flow rate seems to be a better determinant of water quality than temperature. Indeed, the concentration of total organic carbon decreases from very low to medium flow rate, but increases from medium to very high flow rate. However, the opposite pattern should be considered regarding nitrate. Consequently, crossing such data, the present study shows that the probability of exceedance of the French limit of quality for total organic carbon in surface water resources used by SSWS is much higher at low and high flow rates associated, respectively, with high and low temperatures. In the same way, the probability of exceedance of the French limit of quality for nitrate in surface drinking water resources is much higher for medium and high flow rates associated with low temperatures. These findings should be useful for water companies, water industry regulators, health authorities and policymakers. In fact, the present conclusions should allow anticipating on the adaptation of drinking water treatment based on the thermal and hydrological conditions.

[3]Université de Bordeaux 1, LPTC, UMR 5255, TALENCE, France

[4]IFAN, Laboratoire biologie marine,UCAD,, DAKAR, Senegal

In the last decades, West African aquatic ecosystems were strongly impacted by climate change inducing increase of water salinity, and by anthropic activities such as industry, agriculture and intensive fisheries that discharge chemical pollutant in environment. To assess the combined effects of both environmental changes, a multiparametric approach was performed. For this purpose, Black chinned Tilapia (Sarotherodon melanotheron) were sampled during dry and rain period in 8 sites characterized by various contamination and salinity profiles. Levels of pollution by PAHs, PCBs, OCPs in sediments of eight sampling sites were characterized. A set of biochemical biomarkers including biotransformation enzymes (EROD activity and glutathione-S-transferase), oxidative stress indicator (lipoperoxidation), neurotoxicity end-point (brain acetylcholinesterase) and estrogenicity biomarker (circulating vitellogenin) was measured to understand the effects of contamination. Moreover, physiological parameters such as growth rate, condition factor and gonado-somatic index were measured in all tilapia to provide data on effect of environmental conditions on fish physiology. The results of this work shows that the health fish living in West African aquatic ecosystems is impacted by combined effects of chemical pollution and climate change and argue for a better assessment of these ecosystems to prevent furthers degradation.

**CS01B-5**

**Interactive effects of multiple-stressors resulting from habitat degradation and climate change in a model reptile species.**

A Gust[1], A Mcfarland[2], S Wilbanks[1], X Chen[1], G Talent[3], J Quinn Jr.[2], J Perkins[1]

[1]US Army Research and Development Center, VICKSBURG, United States of America

[2]US Army Public Health Command, EDGEWOOD, United States of America

[3]Oklahoma State University, SILLWATER, United States of America

The ability to assess multiple-stressor effects that result from habitat degradation and climate change is crucial for maintaining viable populations and overall ecosystem health. Chemical stressor effects have been relatively well studied but effects have seldom been investigated in conjunction with common stressors that wild populations must endure. For example, field studies have indicated that malarial infections in reptiles positively correlate with increased temperature (a concern regarding global warming) leading to infection incidence as high as 50%, and the interactive potential of increased parasitism in conjunction with additional anthropogenic stressors is yet to be investigated. To approach this question, we utilized the Western fence lizard (WFL, Sceloporus occidentalis) as a model species to characterize multiple-stressor effects projected to be caused by climate change and habitat degradation including: increased malarial parasitism, decreased basic resource (food) availability and exposure to chemical contamination (trinitrotoluene, TNT) to determine the overall interactive-potential of these stressors. To accomplish this, we tested the null hypotheses: (1) Multiple ecosystem-level stressors characteristic of habitat degradation and climate change have no interactive effects on lizard health and fitness, and (2) Environmental stressors are uniquely identifiable via genomic signatures and these signatures can be used to identify predominant stressors in multiple-stressor scenarios. The first hypothesis was tested by evaluating stressor impacts on 29 toxicological endpoints investigated in clinical toxicology bioassays characterizing single-stressor and pairwise-stressor effects. Although few interactive effects were identified, three interactive effects of potential ecological concern were observed: (1) food limitation may eliminate hormesis of TNT on animal weights, (2) combined food limitation and malarial infection may impact immune response as well as (3) impact testes size and quality. To test the second hypothesis, we utilized next-generation DNA sequencing to develop a de novo bioinformatics infrastructure and high-density microarray to assess transcript expression for Western fence lizard. The tools are being used to determine the genomic signature for each stressor and stressor interaction utilizing observed mechanistic and metabolic impacts as the foundation for signature development.

**CS01B-6**

**Climate change damage functions in LCA - (1) from global warming potential to natural environment damages**

I Callesen[1], MZ Hauschild[1], R Bagger Jørgensen[2], SI Olsen[1], C Beier[2]

[1]DTU Management Engineering, LYNGBY, Denmark

[2]Risø-DTU, ROSKILDE, Denmark

Energy use often is the most significant contributor to the impact category 'global warming' in life cycle impact assessment. However, the potential global warming effects on the climate at regional level and consequential effects on the natural environment are not thoroughly described within LCA methodology. The current scientific understanding of the extent of climate change impacts is limited due to the immense complexity of the multi-factorial environmental changes and unknown adaptive capacities at process, species and ecosystem level. In the presentation we argue that the global warming impacts from a product system being studied in an LCA must be seen in context with the changing future background situation. This background situation is among other things affected by e.g. cumulative atmospheric greenhouse gas emissions of yet unknown magnitude. Here, we define climate change damage on the natural environment as climate change driven environmental changes. The man-made environment such as cultivated land, infrastructure and urban areas is not considered.

Hypothetical climate change damage functions representing both sensitive and robust responses were analyzed in relation to cumulative green house gas emissions. An attempt was made to link these hypothetical damage functions with current experimental evidence of biological and biogeochemical responses to a changing growth environment. Each LCA stage involves uncertainty due to e.g. choice, modeling, sampling and measurement errors apart from natural variation. Error propagation throughout the stages of the LCA is thus needed. The relative uncertainty (expressed as the coefficient of variation) of the product related emission, of the background situation and of the natural environment responses were compared. It seemed that the overall relative uncertainty of a characterization factor for climate change might be at least 64%-152% indicating a large variability around the unknown mean climate change damage.

**CS02-1**

**Ship based oil spill monitoring, a new integrated system for thickness estimation and operational overview**

H Skjelten, C Gutvik, LA Solberg
Aptomar AS, TRONDHEIM, Norway

With an increasing number of offshore oil wells, oil spill prevention and recovery receives a growing focus amongst authorities and oil companies. When accidents happen oil spill spreads to form a thin layer at sea surface, and the disaster scene quickly turns extensive and over-complex. Reliable sensor capability and data acquisition systems are critical for an efficient recovery operation. Currently, there are several systems available for detection and monitoring of oil spill, however, it is acknowledged that there are still major shortcomings in terms of giving a comprehensive overview covering everything from on-scene recovery operations to strategic planning. Particularly is it a challenge to provide relevant information to the vessel crew that is operating the dispersant agents, oil booms and skimmers. The present paper outlines a commercially available system, named SECurus, designed to comply this. The system is built around a vessel mounted, motion stabilized sensor platform containing a cooled infrared (IR) camera, daylight camera and xenon searchlight. The IR camera serves two distinct purposes: 1) As a sensor technology for oil spill detection and 2) As a tool for operational overview in combination with the daylight camera for night and day vision. As sensor platform, IR is recognized for providing relative thickness evaluation of oil spill which is critical for prioritizing recovery operations. An open sensor communication interface is developed and tested with 3rd party radar oil spill detection systems. All sensors, including the camera video streams, are geo-referenced and integrated into an electronic chart system (ECS). Computer generated graphics can be transposed between sea chart and camera views with principals from augmented reality. In addition to operational usage at North Sea oil spill response vessels, the system has been extensively tested through planned exercises in collaboration with The Norwegian Clean Seas Association for Operating Companies (NOFO).

**CS02-2**

**Effects of acute oil spills on the Norwegian marine environment**

S Boitsov, BE Grøsvik, S Meier, J Klungsøyr
Institute of Marine Research, BERGEN, Norway

A number of small-to-medium size acute oil spills have occurred in Norwegian waters in the latter years. The Institute of Marine Research (IMR) has performed damage assessment studies after several recent oil spills. Measurements of the levels of oil-related organic contaminants have been carried out in seawater and various biota samples after the spills, with follow-up investigations undertaken half a year to one year later if necessary. The objectives of the studies were to assess the degree of contamination in the marine environment, to monitor the contamination with time, and to quantify the possible damage inflicted on shellfish and commercially important fish stocks.
Oil spills taking place at three locations in Norway in the period 2007-2009 will be discussed:
1. Cargo vessel "Server", wrecked near Fedje, Hordaland in Western Norway in January 2007. The total amount of oil spilled to the environment was 380 tons.
2. The discharge of 4000 tons crude oil at the Statfjord A oil platform in the Tampen region of the North Sea was the second largest discharge till now in Norway after 40 years of exploration. A second, minor spill of 70 m3 oil occurred at the same platform in May 2008.
3. Cargo vessel "Full City"ran aground near Såstein, Telemark in Southern Norway in July 2009. The total amount of oil spilled was 300 tons. The spill has caused a considerable contamination of the nearby coastal area. The study of the consequences of the spill was one of the most detailed undertaken in Norway.
The results of these studies largely lead to the same conclusions. In all cases, an increase in oil-related contaminants (polycyclic aromatic hydrocarbons, PAH, and their metabolites) was demonstrated in various compartments of the environment (seawater; fish liver and in some cases muscle; fish bile; crab, shellfish or shrimp tissue). The levels in the water and mobile biota were not alarmingly high and went relatively quickly back to background levels. The highest levels were found in the organisms that could not escape from the contaminated area (trapped fish, mussels). The overall effect of the spills seemed also to be influenced positively or negatively by external factors, such as poor weather (in the case of "Server"and at Statfjord A in December 2007), or pre-existing contamination from other sources (in the case of "Full City").

**CS02-3**

**Reported in the Gulf of Mexico following the Deep Horizon oil spill; what risk do alkyl-naphthalenes pose?**

AG Scarlett, CE West, R Clough, SJ Rowland
University of Plymouth, PLYMOUTH, United Kingdom

Alkylnaphthalenes (AN) are commonly present following spillages of crude oils and were reported in the Gulf of Mexico following the Deep Horizon platform disaster. They also dominate oil industry produced waters and consequently AN are commonly present as a major component within tissue extracts of marine biota contaminated by petroleum products. Surprisingly, little information concerning the toxicity of AN has been reported and monitoring of hydrocarbons has largely been focused on the USEPA priority pollutant list of 16 polycyclic aromatic hydrocarbons, even though within crude oils, alkyl derivatives are much more prevalent than the parent compounds. We now report the toxicity of a range of commercially-available and specially synthesised $C_{2-8}$ substituted non-branched and branched AN to the mussel, *Mytilus spp*.
Acute (48 h) semistatic exposure tests were performed using test solutions of individual $C_2$-$C_8$ AN and as a mixture. Health effects were assessed using inhibition of mussel clearance (feeding) rate bioassays and critical body residue parameters ($IC_{20}$ and $IC_{50}$) were derived. Depuration studies (5 d in clean seawater) were also performed. In addition, tissues from mussels exposed to aromatic fractions from a weathered and a biodegraded crude oil, and that from wild North Sea (UK) mussels, were extracted and analysed by tandem gas chromatography (GCxGC-TOF-MS), and the accumulation profiles of the bioaccumulated AN compared.
The lower molecular weight compounds ($C_{2-3}$) were found to have similar toxicities to each other, whether mono- or di-substituted. The $C_4$ compound 2,6-diethylnaphthalene was significantly less toxic (P<0.05). Tissue $IC_{50}$s for the $C_{2-3}$ compounds were very close to the QSAR models for mussel clearance rates, but higher molecular weight compounds were far less toxic than model prediction. An exception to this was the synthesised $C_8$ branched AN, 2-(1',5'-dimethylhexyl) naphthalene, which reduced clearance rates to a similar extent to the lower molecular weight AN implying that the structure of the AN and not just the molecular weight or hydrophobicity, is important. Mussels were generally able to rapidly recover from exposure to AN. Profiles of accumulated AN were similar within oil-exposed and contaminated wild mussels.
Marine environmental monitoring should include measurements of AN but our results suggest that other compounds are perhaps more likely to bioaccumulate, persist and pose a longer term threat to marine biota.

**CS02-4**

**Effects of oil and oil treated with dispergent on the arctic amphipod Gammarus setosus**

JF Børseth[1], T Baussant[1], A Ingvarsdottir[1], LG Faksness[2], BH Hansen[2], C Lucas[1], AHS Tandberg[1]
[1]IRIS Biomiljø, RANDABERG, Norway
[2]SINTEF, TRONDHEIM, Norway

When oil is released in an area with ice we will face a complex interaction between oil, water and ice. The oil will be absorbed by snow on the ice edges, it may be trapped in the ice in brine channels and it may be moved underneath the ice. The ice field as such will also be under constant transformation driven by wind, currents and temperature. Some ice floes may be transported relatively far from their original position and relatively far from their original neighbors. Alltogether this may be a strong driving force for drift and spread of oil after oil has been released in an ice field.
These processes have been followed during an offshore field experiment in the marginal ice zone East of Svalbard in May 2009 [1] and basic field data have been used to accomplish a realistic and relevant exposure study in the laboratory. Chemical results from analyses of water samples of the laboratory exposure experimnt showed good correlation with identical data monitored during the offshore field experiment with oil in ice infested seawater. Due to the low input of energy during the exposure period in the laboratory study, there were no indications of oil droplet formation in the water fraction caused by the dispergent. However, levels of naphtalenes were relative high. Among the effect markers, general stress was indicated by a significant decrease in lysosomal stability of ampipod haemocytes in the oil+dispergent treatment.

**CS02-5**

**Ecotoxicology and risk assessment of crude oil spill in a palm oil plantation**

INE Onwurah[1], OF Otitoju[2]
[1]University of Nigeria, Nsukka, NSUKKA, Nigeria
[2]University of Uyo, UYO, Nigeria

This report is a quantitative/qualitative impact assessment of the effect of the massive crude oil spill that occurred in October 03, 2006 on a parcel of land having nine thousand, five hundred (9,500) matured oil palm trees. An assessment of the impact was based on the observed changes in relevant valued ecosystem components (VECs), using biochemical end point parameters from both laboratory and field study of the spill environment, multiple-lines-of-evidence approach and consideration of the relevant literature. The toxicity of the spilled oil was evaluated using lumbricus species (earthworms) and diazotrophic bacterium Azotobacter vinelandii found in ecosystem. Exposure of earthworms to the crude oil-contaminated soil samples taken from the palm plantation three months and one year after the spill resulted in 68 - 76 % death and significant loss in weight in those surviving after 96 hours. Relatively very low number distribution of earthworms was observed in the oil polluted plantation when compared with control (unpolluted) site and with significant bioaccumulation of the PHC in the earthworms. There was a significant reduction in nitrogen fixation in soil cores taken from the oil-contaminated oil palm plantation and also in population and distribution of Azotobacter vinelandii. There was a significant reduction ($p < 0.05$) in the chlorophyll content in samples of fresh palm leaves taken from the polluted palm plantation, between February 2007 and December 2007 when compared with the control site, thus suggesting that the toxic effects of the crude oil spill exerted and is still exerting a considerable impact on the yield capacity of the oil palm trees and the ecosystem productivity. There was a good correlation in chlorophyll content of the maize planted in simulated oil-contaminated soil and the yield in maize grain and this was made manifest in the yield of maize planted in parallel uncontaminated plots. Based on the above correlation, it was concluded that the crude oil spill in the plantation negatively affected the productive capacity of the palm trees and the plantation ecosystem in general.

**CS02-6**

**Deriving disaster impact distances for 'Seveso'-companies in relation to protected nature areas**

E Brand[1], L Posthuma[1], M van de Meent[1], N van den Brink[2], H den Hollander[1], D de Zwart[1]
[1]National Institute for public health and the environment (RIVM), BILTHOVEN, The Netherlands
[2]Alterra, WAGENINGEN, The Netherlands

After the disaster at Seveso Italy in 1976 legislation was developed to protect humans and the environment from industrial accidents. This ultimately resulted in the development of the so called Seveso II directive (Council Directive 96/82/EC on the control of major-accident hazards).
EU-member states are obliged to bring this directive into force in the national laws. In the Netherlands this resulted in the Regulation to assess distances to nature areas, in short called Reban, which became active in 2006.
Reban states that there needs to be a "sufficient distance between heavy industry and vulnerable nature areas in case of an industrial disaster". To determine this distance there "needs to be an appropriate tool that can determine distances between the industry and nature". The Dutch government would provide such a tool to execute risk analyses. The National Institute for Public Health and the Environment (RIVM) was asked to develop this tool.
Seveso companies working with the most hazardous chemical compounds require a permit for new installations or expansions of facilities when positioned in the vicinity of protected nature areas. Risk analyses must make clear, that sufficient distance is kept between the facilities and the nature areas in case of an industrial accident.
A tool to assess this distance has to contain fate and effect assessment, to deliver critical distances when combined with regulatory acceptance criteria on maximum allowable exposures. Comparison of a critical distance with the geographical distance between facility and nature area provides insight in the matter of sufficient distance. The approach is to be applied in cases for so-called Seveso-facilities near nature areas specifically protected under the Nature protection act, including Natura 2000 nature areas.
This presentation considers a tool which has been designed to evaluate the ecotoxicological risks imposed by Seveso-facilities which can be positioned in the vicinity of protected nature areas. For those areas, the ecological vulnerability is explored with the tool. Through realistic disaster scenario's compounds, we explore the resulting distributions of impact distances, and compared these with realistic distances between Seveso facilities and protected nature areas on GIS maps. We show how the critical distance concept can be used together with ecological vulnerability analyses to conclude whether a facility can be considered to be at a safe distance or not.

## CS03 - New approaches in the simulation of realistic multistress and multispecies scenarios

**CS03-1**

**Sensitivity shift in Daphnia magna population response caused by size selective predation**

A Gergs, S Riehm, TG Preuss
RWTH Aachen University, AACHEN, Germany

The quest for more realism in ecological risk assessment demands for looking beyond ecotoxicological standard tests by additionally considering e.g. population structure, competition or predation. Predation is considered to be a major factor controlling dynamics and structure of freshwater comunities.The outcome of predation varies with both prey size and predator size, thus mostly appears to be size selective. Moreover, body size affects an animal's sensitivity to toxicants, e.g. it is known for *Daphnia magna* that neonates in general are more sensitive than adults.
In order to analyse combined effects, we simulated the population dynamics of *D. magna* under predation and toxic stress and compared the model output to laboratory data. As a predator, larvae of the backswimmer *Notonecta maculata* were used. For modelling *Daphnia* population dynamics and *Notonecta* predation we applied two individual based models which were already shown to adequately predict different scenarios.
In the laboratory, we tested the effect of p353-Nonylphenol (Np) on populations of *D. magna* under predation pressure. Population dynamics, including size structure, were recorded for 4 different treatments during 11 weeks: {1} control populations, {2} populations under predation, {3} populations exposed to two peaks of Np and {4} populations under predation and exposed to two Np peaks. Single larvae of *N. maculat*a were placed in prepared aquaria after *D. magna* populations reached peak abundance. During test backswimmers grew from first to fith instar.
In both, modelling approach and laboratory study predation was found to significantly alter *Daphnia* population size and structure. Since size selectivity differs across *Notonecta* instars, the impact on *Daphnia* populations changed during development of the predator and was highest in large backswimmers. Under predation of larger backswimmers, size structure of *Daphnia* populations shifted towards higher number of neonates and lower numbers of adults compared to control. Thus the combined effect of predation and toxicant finally led to the extinction of *D. magna* populations, whereas total abundances of other treatments were similar to or above control level. We will demonstrate that multiple stressors may result in severe effects on population level, which are not predictable from single stressors and that mechanistic modelling might be an appropriate tool for predicting the combined effects in environmental risk assessment.

**CS03-2**

**Daphnia under stress: a case study**

M Jansen[1], R Stoks[1], A Coors[2], L de Meester[1]
[1]K.U.Leuven, LEUVEN, Belgium
[2]ECT, FRANKFURT, Germany

Natural populations worldwide are increasingly exposed to pesticides. This may not only impact target pest species but also a wide variety of non-target species, including keystone species that are crucial to the functioning of natural ecosystems. Pesticides impose strong selection pressures on natural populations. This may lead to the evolution of resistance, which itself may be associated with correlated responses, including potential costs of evolution. Populations are also exposed to natural stressors like parasites and predators, and these stressors may interact simultaneously with pesticide exposure. While studies on local genetic adaptation and costs of evolution are rare in non-target species, studies on direct interactions between stressors, especially when dealing with biotic stressors, are typically implemented in non-target species.
We used the water flea *Daphnia magna*, a non-target species often used as a model system in ecotoxicology, in an integrated research approach in which we focussed on three aspects that are of key importance to understand the evolutionary ecology of pesticide exposure: (1) the capacity of natural populations to genetically adapt to pesticide exposure, (2) the added complexity of synergistic effects caused by simultaneous exposure to natural stressors, and (3) the potential interference of evolutionary costs of adaptation to pesticide exposure. In a next step we tried to understand the mechanistic base of the observed responses using a cDNA *Daphnia magna* microarray.

**CS03-3**

**Will climate change uncover low-dose effects of pesticides? A multigenerational study with the midge Chironomus riparius**

R Müller[1], A Seeland[1], L Jagodzinski[2], J Diogo[1], C Nowak[1], J Oehlmann[2]
[1]LOEWE Biodiversity and Climate Research Centre, FRANKFURT AM MAIN, Germany
[2]Goethe University, FRANKFURT AM MAIN, Germany

The potential risk of pesticides under climate change conditions is not yet accurately assessable for aquatic wildlife. We hypothesize that near-natural dynamic temperature regimes may uncover the ecotoxicity of low dosed pesticides due to the concomitant successive exposure to suboptimal and optimal temperatures, in particular under impact of climate change.
The hypothesis was tested by performing a bifactorial multigenerational study with the aquatic model organism *Chironomus riparius*, which has been chronically exposed to a low dose of the fungicide pyrimethanil under two dynamic present-day temperature simulations (cold year today: 11.0-22.7-18.6°C, warm year today: 14.0-25.2-21.7°C) and one future scenario (warm year in future: 16.5-28.1-24-1°C). During the 140-days-lasting multigenerational study covering spring and summer season, parameters related to survival, emergence, reproduction, population growth and genetic diversity of C. riparius were analysed.
In general, life-history-traits of *C. riparius* are highly dependent on temperature and generational time. In simulated spring, a ´no-effect-concentration´ (NOEC) of pyrimethanil provokes slightly adverse or hormetic effects on *C. riparius* in three temperature scenarios (P- to F1-generation) as expected from standard test. But an exposure of *C. riparius* to a NOEC of pyrimethanil at a thermal situation likely for a present-day or future warm summer (F2-generations onwards) uncovers considerable adverse effects on mortality and genetic diversity. Under the simulated climate change situation, pyrimethanil-treated C. riparius reveal the highest mortality, a substantially reduced population growth rate and a sizeable loss of genetic diversity. Although adverse pyrimethanil effects vanish until the end of the summer in both present-day scenarios, *C. riparius* sub-populations (control, pyrimethanil treatment) exposed to the climate change scenario break down after F3-generation.
The results gained so far highlight the importance of near-natural climate impact research to better understand and manage the ecotoxicological risk of agrochemicals today and in future. Not only the impact of climate change, but also considered safe concentrations of pesticides may pose a reasonable risk for aquatic insects in future.

**CS03-4**

**Effects of imidacloprid pulses on macrozoobenthos in lentic microcosms**

V Colombo[1], R Berghahn[2], S Loth[2], VJ Pettigrove[1]
[1]University of Melbourne, MELBOURNE, Australia
[2]Federal Environment Agency, BERLIN, Germany

Over the past decade the use of a new generation of insecticides, the Neonicotinoids, has been marketed strongly. Imidacloprid was a best seller thanks to its low application rates, high activity against pests and fast degradation. However, because of its high solubility in water it has the potential to enter surface waters. In the risk assessment tests were conducted under laboratory conditions, based on single species and continuous-exposure scenario. In agricultural areas, periods of peak application followed by rainfall events can lead to pulse contaminations, where concentrations can reach toxic levels for non-target invertebrates. The aim of this study was to assess the impact of Imidacloprid pulses on non-target aquatic macroinvertebrates. To achieve realistic exposure conditions the experiment was carried out using infield microcosms. This method is designed to simulate natural lentic ecosystems and enables the testing of many indigenous invertebrates developing within microcosms. During the experiment optimal conditions for Imidacloprid degradation prevailed, therefore this experiment has to be considered a 'best case' rather than a 'worst case' exposure scenario. Measurements on structural aspects of the macrozoobenthos showed some evident responses: At the greatest concentration tested (nominal concentration 40 μg/L) diversity and abundance of some taxa (e.g. Chironomidae) decreased; the emergence of some chironomids species and of Ephemeroptera declined at the highest concentrations tested (nominal concentrations: 17.3 and 40 μg/L). The results provide evidence that despite rapid dissipation short-term exposures to imidacloprid can significantly affect the structure of freshwater ecosystems, even at low concentrations. The microcosms method showed also to be a valuable tool in the risk assessment of contaminants.

**CS03-5**

**Combined effects of pesticide exposure and predation risk: what can we learn from behaviour and physiology?**

CT Janssens, R Stoks
Katholieke Universiteit Leuven, LEUVEN, Belgium

To assess the impact of pollutants in field situations we need to understand whether their effects are magnified when combined with natural stressors like predation risk. Such synergistic interactions sometimes occur but we do not understand when to expect and how to explain these. One way to advance is to start unraveling jointly affected behavioural and physiological end points of combined exposure to pesticides and predation risk. To this aim we investigated in larvae of the damselfly Enallagma cyathigerum the joint effects of pesticide exposure (glyphosate) and predation risk (visual and chemical predator stimuli) on growth and associated behavioural (food intake) and five (sets of ) physiological variables:.(1) expression levels of the stress protein Hsp70, (2) the activity of two key antioxidant enzymes in insects, superoxidedismutase (SOD) and catalase (CAT), (3) the degree of oxidative damage to lipids as quantified by levels of lipofuscine and TBARs, (4) the levels of energy reserves: proteins, sugars (glucose and glycogen) and total fat, and (5) the activity of acetylcholinesterase (AChE), an enzyme strongly linked to the efficiency of nerve signal transmission. There was a strong synergism on growth: the pesticide only caused a growth reduction in the presence of predation risk. This growth synergism was not behaviourally mediated as food intake was higher in the presence of the pesticide and not influenced by predation risk. All five (sets of ) physiological variables were affected by isolated exposure to predation risk but only one by isolated exposure to the pesticide (upregulation of Hsp70). Pesticide exposure did, however, interact with predation risk for oxidative stress and oxidative damage: SOD was only influenced by the pesticide in the presence of predation risk and TBAR levels only increased in larvae that were jointly exposed to the pesticide and predation risk. Together, this suggests that under combined stress exposure the larvae were not able to react to the associated oxidative challenge by upregulation of SOD and CAT, and as a result encountered damage, namely the peroxidation of fat. This may have contributed to the observed synergistic growth reduction. Such combined behavioral and physiological approach is therefore a promising avenue to increase our understanding of when such synergisms are to be expected.

**CS03-6**

**Assessment of soil contaminants bioavailability using a multi-marker approach in laboratory and field experiments**

PY Robidoux, V Bérubé, Y Berthelot, M Blanchard, K Savard, GI Sunahara
National Research Council of Canada, MONTREAL, Canada

Simultaneous contamination of soil by various substances (contaminant mixtures) presents a challenge for risk assessment. Chemistry analyses give the level and type of contaminants. Toxicity tests assess the effects of bioavailable compounds to selected species using standard important endpoints (survival, growth, fertility). Bioavailability can be defined as "the fraction of a substance that will exert an effect in a organism". This fraction is "toxicologically bioavailable". Conversely, bioaccessibility is referred to as "the fraction of a substance which is readily mobilizable by an organism in a soil". Bioavailability is critical for understanding effects that might result from exposure of biota to contaminated soils and sediments. Soils and sediments from military range and training areas (RTAs) as well as Munitions Experimental Test Center (METC) are contaminated principally by energetic materials (EM) and metals. Their chemical characteristics are relatively well known and toxicity assessment of soils from RTAs and METC are in some cases available. However, bioavailability on these sites needs to be comprehensively characterized. Conventional toxicity tests give limited toxicological information and do not consider variability (e.g., temperature, humidity) of current and future field conditions. Improvement of standard assays by adding alternative biological endpoints (cellular, biochemical, molecular biomarkers) can help to understand the toxicity observed and give the appropriate information for the selection of biological parameters for other tier assessment levels (e.g., field mesocosm assays, field studies) where standard chronic endpoints can not be used. Use of selected biomarkers alone gives appropriate information on chemical stress, range and class of contaminants, and health status. This paper presents case studies using laboratory and field bioassays and an integrated approach including earthworm (Eisenia andrei) toxicity tests and a suite of biomarkers and chemical analyses. Parameters such as lysosomal membrane fragility of cð'lomocytes (neutral red retention time) can be used to assess the chemical stress whereas the antioxidant system (catalase and superoxide dismutase activity) and detoxification metabolism (glutathione S-transferase activity, metallothionein), as well as the immune activity and the contaminant uptake are used to assess the bioavailability of contaminants and the health status of the exposed organisms.

## EC01 - Advances in passive sampling and dosing techniques

**EC01A-1**

**A decade monitoring of PCBs and PAHs by silicone rubber passive samplers in parallel with**

**deployed mussels**

F Smedes[1], K Koning[2], M Kotte[2], S Vliet[2], K Booij[3]
[1]Deltares, UTRECHT, The Netherlands
[2]Rijkswaterstaat, Centre for Watermanagement, LELYSTAD, The Netherlands
[3]Royal Netherlands Institute for Sea Research, TEXEL, The Netherlands

Since the introduction of passive sampling in the aqueous environment two decades ago, many research papers have been published. However, most of the monitoring studies performed with passive samplers were one-off surveys and programs covering several years are very rare. Here a decade monitoring in autumn and winter with Silicone Rubber Passive Sampling (SRPS) in parallel with deployed mussels (Mytilus edulis) running from 2002 at eight Dutch coastal stations will be discussed. Results were processed using the latest partition coefficients and models for calculation of the concentrations in the water phase. Sampling rates were clearly lower in winter when the water temperature was lower. The average of the estimated concentrations of PCBs in the water phase ranged from 3 pg $L^{-1}$ (PCB170) - 40 pg $L^{-1}$ (PCB52). Concentrations of PAHs in the water phase ranged from ~10 pg $L^{-1}$ (indeno[1,2,3-cd]pyrene) to 4000 pg $L^{-1}$ (phenanthrene). Estimated concentrations were higher in winter compared to autumn, for PCBs as well as PAHs. Comparing amounts per mussel before and after exposure reveals that in about 20% of the cases contaminants were released during exposure. Although this is no evidence that equilibrium is attained it does mean that data are likely positioned on both sides of the equilibrium.The resulting lipid based bioaccumulation factors (LBAF) were evaluated and showed more variation in winter compared to autumn. Furthermore, also the LBAFs for PCBs were on average significantly lower in winter compared to autumn. Relating LBAF to the water temperature showed a decrease of LBAF with temperature (~0.04 log units). Such a decrease was not found for PAHs. Lower LBAFs in winter for PCBs were mainly caused of the higher concentrations calculated or the water phase and not, or much less, by changes in the concentrations in the mussels. In spite of the observed temperature effect, that only became significant because of the large dataset, the log LBAF values show an excellent relationship with logKow values. Further fine tuning of research that relates passive sampling to uptake by mussels should take the water temperature and salinity into account for the passive sampling as well as uptake by mussels.

**EC01A-2**

**New developments in passive air sampling for current-use pesticides and other priority chemicals**

M Koblizkova, T Harner, SC Lee, S Genualdi
Environment Canada, TORONTO, Canada

Passive air samplers are cost effective and simple tools that are invaluable for assessing risks associated with pesticide use. They can be used to monitor and evaluate regional and long range transport of pesticides and provide spatially resolved data that is required for developing transport and fate models. Under the Global Atmospheric Passive Sampling (GAPS) network, passive air samplers comprising polyurethane foam (PUF) disks are being used to deliver air concentrations of several organochlorine pesticides at more than 50 global sites. The value of these samplers has been recognized and there is a need to extend their application to more volatile and polar pesticides that are typically used these days. This study investigates a modified PUF disk sampler, the SIP (or sorbent-impregnated PUF) disk which used XAD powder impregnated into the PUF to enhance sorptive capacity. An eight-month field calibration study of the PUF disk and SIP disk samplers has been undertaken during 2010 to establish sampling rates and sorptive capacities for a range of current-use pesticides that are relevant to Canada. Preliminary results are also available from the first deployment of the SIP disk sampler at a subset of 20 GAPS sites alongside the conventional PUF disk sampler. This study provides the first global-scale survey of several classes of priority chemicals, including CUPs. The GAPS network also includes several urban sites (e.g. Toronto, Canada; Paris, France). These locations can be compared to background and agricultural areas and this may provide useful information about transport of CUPs from application areas.

**EC01A-3**

**EU-wide environmental monitoring of Persistent Organic Pollutants using butter as biomonitoring matrix**

JM Weiss, G Mariani, L Amalfitano, I Vives, A Mueller, H Skejo, G Umlauf
JRC, ISPRA (VA), Italy

Lipids are good matrices to accumulate many persistent organic pollutants (POPs) due to the lipophilic nature of these chemicals. Dairy products are easily accessible and available world-wide and analysis of this matrix reflects the contamination level of the environmental compartment from which they derive.The Stockholm Conventions and the Global Monitoring Plan (GMP) encourage the production of monitoring data to effectively evaluate the presence of the POPs in all regions, in order to identify changes in levels over time, as well as to provide information on their regional and global environmental transport.
Suitable sample matrix is needed to measure the temporal and spatial distribution of the priority POPs, which are both intentional and unintentionally released to the environment. Passive sample techniques have been applied to the GMP monitoring activities to assess the global long range transport of POPs. The data produced by passive samplers have been shown to correspond to the more advanced active air sampler. The advantage with passive air sampling is that no advanced equipment demanding electricity is needed. The samplers can therefore be set up everywhere, even at remote areas. But still some education of the personnel is needed to operate the sampler. Aspects such as wind direction, temperature and sampling time are crucial to register and incorporate into the calculations.
In this study we demonstrate the feasibility to use another passive sample approach for screening purposes, i.e. animal lipids such as butter. The advantages to use butter as biomonitoring matrix are several; due to the lipophilic and persistent properties of POPs they are bioaccumulated in lipid rich matrix; butter reflects the contamination level of the environmental compartment from which they derive due to well known transfer factors; butter is available in almost all geographic regions and is cheap and easily accessible; moreover, this biomonitor is well buffered against temporal variations. The air-grass-cow transfer factors are available from controlled experiments. Hence it remains to verify the correlation in the field in order to assess ambient air quality. The POP levels of 160 samples from Europe have been analyzed and will be evaluated together with available air data to establish a correlation between air contamination and dairy products (assuming minimal commercial feed contamination influence).

**EC01A-4**

**Determination of deployment specific chemical uptake rates for SDB-RPS Empore disk using a passive flow monitor (PFM)**

DS O'Brien[1], M Bartkow[2], JF Mueller[1]
[1]The University of Queensland, BRISBANE, Australia
[2]Queensland Bulk Water Supply Authority trading as Seqwater, BRISBANE, Australia

The use of the adsorbent SDB-RPS-EmporeTM disk in a Chemcatcher type passive sampler is routinely applied in Australia when monitoring herbicides in aquatic environments. One key challenge in the use of passive samplers is mitigating the potentially confounding effects of varying flow conditions on chemical uptake by the passive sampler. Performance reference compounds (PRCs) may be applied to correct sampling rates (Rs) for site specific changes in flow and temperature; however, evidence suggests the use of PRCs is unreliable when applied to adsorbent passive samplers. The use of the passive flow monitor (PFM) has been introduced for the assessment of site specific changes in water flow. In the presented study we have demonstrated that the Rs at which both atrazine and prometryn are accumulated within the SDB-RPS-EmporeTM disk depend on the flow conditions. Further, the calibration of the measured Rs for chemical uptake by the SDB-RPS-EmporeTM disk to the mass lost from the PFM has shown that the PFM provides an accurate measure of Rs for flow velocities from 0-16 cm s-1. Notably, for flow velocities > 16 cm s-1, a non linear increase in the Rs of both herbicides was observed which indicates that the key resistance to uptake into the SDB-RPS EmporeTM disk is associated with the diffusion through the overlying diffusion limiting membrane. Overall the greatest uncertainty remains at very low flow conditions which are unlikely to occur often in surface waters. Validation of the application of PFM has also been undertaken in a limited field study.

**EC01A-5**

**Effective in-situ measurement of pore water PCB concentrations in sediment profiles using passive samplers**

AMP Oen[1], EML Janssen[2], G Cornelissen[1], RG Luthy[2]
[1]NGI, OSLO, Norway
[2]Stanford University, STANFORD, United States of America

Since their introduction, the use of passive samplers to measure freely dissolved concentrations of hydrophobic organic compounds (HOCs) in aquatic environments has become more prevalent. However, there are limited studies that have utilised passive samplers to assess in-situ pore water concentrations. Measurements of pore water concentrations are important as they are a more appropriate indicator of the bioavailable contamination in an ecosystem. This study focuses on measuring sediment pore water concentrations of polychlorinated biphenyls (PCBs) in an AC amended contaminated sediment site by: (i) measuring vertical pore water profiles of PCBs from 0-50 cm using both polyethylene devices (PEDs) and polyoxymethlyene (POM), (ii) dosing the passive samplers with a larger suite of performance reference compounds (PRCs), and (iii) interpreting PRC depletion to assess the development towards equilibrium. In August 2008, sampling rods with ultra thin POM (17 _m) and polyethylene (PE) were placed in a remediated sediment treatment plot located in a tidal mudflat area of the South Basin in San Francisco Bay. The sampling rods were deployed in a radial pattern at each location and were retrieved over time. In order to assess the approach towards equilibrium, the PE and POM passive samplers had been impregnated with PRCs. Three different methods were used to estimate the pore water concentrations: (a) assuming equilibrium has been achieved in the POM after 100 days of exposure, (b) depletion of PRCs from the PE and assuming a first-order process uptake model and (c) depletion of the PRCs from the POM assuming a first-order process uptake model. Average pore water concentrations ranged from 0.4-5.2 ng/l in the top 30 cm of sediment and from 0.9-9.2 ng/l in the deeper sediment layers (30-40 cm) depending on passive sampler material and the method used to interpret to depletion of PRCs. The close agreements of pore water estimates for the two sampler materials (PE and POM) and the different methods used to derive pore water concentrations demonstrate the robustness and suitability of the passive sampling approach. Better understanding of the performance of different sampler materials and uniformity in methodologies to calculate pore water concentrations considering the dissipation of PRCs will allow sediment managers and researchers to make a well informed choice for monitoring and study designs.

**EC01A-6**

**Development and use of polyethylene passive samplers to detect triclosans and alkylphenols in an urban estuary**

VP Sacks, R Lohmann
University of Rhode Island, NORTH KINGSTOWN, United States of America

To be able to use polyethylene passive samplers (PE) in the field, the partitioning constants between PE and water ($K_{PEw}$) of the compounds examined must be known. The $K_{PEw}$s of triclosan (TCS), methyl triclosan (MTCS), n-nonylphenol (n-NP), n-octylphenol (n-OP), and t-octylphenol (t-OP) into PE were measured as a function of pH, temperature, and salinity, and a salt effect was calculated for TCS, n-OP and t-OP. Log $K_{PEw}$s used for calculating dissolved concentrations were taken from 20 C studies taking salt into account: 3.42 (TCS), 4.45 (MTCS), 4.13 (n-NP), 3.68 (n-OP), and 2.87 (t-OP). As expected, the $K_{PEw}$ of hydroxyl-group containing compounds were strongly affected by pH, whereas MTCS with its methylated hydroxyl-group was not. Measured $K_{PEw}$s could not be estimated from octanol-water partitioning constants due to the semi-polar makeup of the compounds investigated. Instead, a good correlation ($K_{PEw}$ = 0.679 * $K_{hdw}$ + 1.033, $r^2$=0.984, p=0.001) was obtained with hexadecane-water partitioning constants ($K_{hdw}$) predicted from COSMOtherm. During deployments in Narragansett Bay (RI) in the fall of 2009, concentrations of MTCS and t-OP in surface and bottom waters ranged from 50 - 270 pg $L^{-1}$ and 3.5 - 11 ng $L^{-1}$ respectively. These concentrations are far below $EC_{50}$ values for rainbow trout. Surface/bottom and bottom/porewater activity ratios were calculated, which indicated surface waters as the main source of MTCS, while surface water as well as sediments were sources of t-OP.

**EC01B-1**

**Air concentrations of current use pesticides (CUPs) in Tuscany and Lazio region, Central Italy, using passive air sampler (PUF disk)**

KAPG Pozo[1], VHE Estellano[1], TH Harner[2], MMM Monti[1], SC Corsolini[1], JB Banghera[3], SF Focardi[1]
[1]University of Siena, SIENA, Italy
[2]Environment Canada, TORONTO, Canada
[3]University of Valle, CALI, Colombia

Very little is known regarding the use and levels of pesticides in Italian agricultural regions. Passive air sampler (PAS) comprised of polyurethane foam (PUF) disk were deployed at four sites in the agricultural areas of Montalcino (Tuscany region) and four sites in Terracina (Lazio region) to asses air concentrations of current use pesticides (CUPs). From twelve CUPs screened only 6 were routinely detected in samples (Chlorpyrifos ethyl, Chlorpyrifos methyl, Trifluralin, Clorothalonil, Pendimethalin, and Chlortal-dimethyl). At Montalcino, air concentrations (pg/m3) of Chlorpyrifos (ethyl and methyl) ranged from 3-80, and Pendimethalin ranged from 1-90 followed by Trifluralin 2-20, and Chlorotalonyl 1-5. Chlortal-dimetyl was not detected at this sampling site. These results are lower than those reported in other agricultural areas of the world. However, at Terracina air concentrations were higher than those detected at Montalcino. Air

concentrations (pg/m3) of Pendimethalin ranged from 30-1000 and Chlorpyrifos ranged from 70-10 000 (~10 ng). At Montalcino, seasonal patterns shows that Pendimethalyn was detected only during period 1 and 2 while Chlorpyrifos (ethyl and methyl) showed the uniform distribution during the whole year at all the sampling sites. The seasonal variation of CUPs were less defined at Terracina. Nevertheless, Trifluralin showed a similar patter of pesticide use at both sampling sites with highest concentrations during period 3. The differences observed at the sites might be related to the different agricultural practices. At Terracina, there is a prevalence of conventional agriculture and the use of a wide range of pesticides. However at Montalcino there is a long tradition for organic farming activities.

### EC01B-2

**Estimating community consumption of Illicit drugs using passive samplers (POCIS) to monitor municipal wastewater**

CD Metcalfe[1], HL Li[1], BA Taylor[1], VL Yargeau[2]
[1]Trent University, PETERBOROUGH, Canada
[2]McGill University, MONTREAL, Canada

Monitoring with the Polar Organic Contaminants Integrative Passive Sampler (POCIS) in untreated municipal wastewater may be a tool for accurately estimating community consumption of illicit drugs and other drugs of abuse. We conducted an evaluation of the capacity of POCIS to monitor municipal wastewater for estimates of community consumption of cocaine and its major metabolite, amphetamine drugs, and prescription and illicit opioids. We estimated POCIS sampling rates between 0.1 - 0.3 L/d for the analytes in laboratory studies, and deployed POCIS in untreated wastewater at two wastewater treatment plants (WWTPs) in Canada to estimate community drug consumption. The results were generally consistent with data generated by monitoring 24-h composite samples of the untreated wastewater.

### EC01B-3

**Pharmaceuticals, personal care products, and agrochemicals in a rural Canadian watershed via passive and active sampling**

CS Wong[1], JC Carlson[1], JE Low[1], JK Challis[1], ML Hanson[2]
[1]University of Winnipeg, WINNIPEG, Canada
[2]University of Manitoba, WINNIPEG, Canada

A suite of 44 pharmaceuticals, personal care products, and agrochemicals were measured in sewage lagoons and surface receiving waters of Dead Horse Creek, Manitoba, a rural tributary of the Red River draining into Lake Winnipeg. These chemicals were monitored via both active grab sampling and passive sampling using the Polar Organic Chemical Integrative Sampler (POCIS), to determine the capability of both types of sampling in characterizing releases from periodic pulse discharges of sewage lagoon waters to the watershed, and to delineate levels and post-release fate of both human point source and agricultural and veterinary non-point source inputs of these chemicals. Major agrochemicals found were atrazine and 2,4-D, consistent with the heavy agricultural land use in the watershed. These chemicals were not observed in wastewaters, indicating negligible inputs home garden and ornamental use. Trimethoprim was observed upstream of known wastewater outfalls, indicating non-point veterinary release from runoff. Carbamazepine and gemfibrozil were observed in surface waters at concentrations up to 200 ng/L only downstream of lagoon outfalls and only during sewage release, indicating human point sources only. Time-weighted-average concentrations from POCIS were consistent with concentrations from instantaneous grab sampling, indicating that POCIS was capable of adequately capturing pulse inputs of contaminants to surface waters in an integrative, continuous manner.

### EC01B-4

**Can monitoring for WFD and MSFD be undertaken using passive samplers?**

JL Balaam[1], P Bersuder[1], J Dobson[2], A Gravell[3], B Lyons[1], C Robinson[4], F Smedes[5], L Steven[2], R Thomas[6]
[1]Cefas, LOWESTOFT, United Kingdom
[2]SEPA, EDINBURGH, United Kingdom
[3]Environment Agency, LLANELLI, United Kingdom
[4]Marine Scotland Science, ABERDEEN, United Kingdom
[5]Deltares, UTRECHT, The Netherlands
[6]NIEA, BELFAST, United Kingdom

Contaminant monitoring for priority pollutants is an integral part of the UK obligations under the Water Framework Directive (WFD) and OSPAR monitoring programmes. Also, the Marine Strategy Framework Directive (MSFD) requires Good Ecological Status (GES) be maintained. Descriptor 8 of GES states that concentrations of contaminants are at levels not giving rise to pollution effects.

It is therefore important to establish whether environmental concentrations of chemicals on existing EC and OSPAR chemical priority lists (e.g. those used to determine chemical status under the WFD) are of toxicological significance, and whether there are additional substances with potential to cause harm in the UK marine environment.

In order to inform this process, passive samplers (silicon rubber and POCIS) were deployed to provide information on presence and freely dissolved concentrations of a wide range of potential target substances for monitoring programmes. The survey covered a wide range of locations around the UK, from industrial estuaries to relatively unimpacted offshore waters. Samplers were deployed for periods of 4 - 8 weeks during spring and summer 2009. In a smaller subsequent follow-up survey, samplers were also deployed alongside mussels. The mussels were analysed for priority substances as well as for effects such as stress on stress, DNA damage, neutral red and a number of biomarker via qPCR.

The presentation will focus on the value added by using these techniques over traditional monitoring techniques and what changes to current procedures or measures may be pertinent given the results obtained, in order to achieve good environmental status.

### EC01B-5

**Sampling of organic pollutants in marine waters using continuous flow integrative samplers and semipermeable membrane devices**

VM León[1], J Llorca[2], R Moreno-González[1], R Tortajada[2], I Valor[2]
[1]Instituto Español de Oceanografía, MURCIA, Spain
[2]LABAQUA S.A., ALICANTE, Spain

The determination of organic pollutants in the environment is relevant for the evaluation of the environmental status. The presence of organic pollutants in the water column has great fluctuations as a result of a combination of natural and anthropogenic effects. Indeed, the hidrofobicity of these compounds favours their sorption on particulate material and their bioaccumulation. For these reasons bivalves are commonly used in the marine international monitoring programs to evaluate the water column contamination. However as an alternative tool, last decades multitude of passive sampling devices and set-ups are being developed to get a representative water sample. Passive sampler accumulates contaminants as an organism from the environment, being proportional to concentration and time of exposition. The most commonly used device is the semipermeable membrane device (SPMD), that use low density polyethylene membrane for the determination of organic pollutants in surface, ground and marine waters. Recently other innovative integrative samplers have been developed with high sampling rates unaffected by turbulences and with negligible lag values, such as the continuous flow integrative sampler (CFIS), which use polydimethylsiloxane (PDMS) for the determination of polycyclic aromatic hydrocarbons (PAHs) and organochlorine compounds.

In this study, the efficiency of two integrative samplers (SPMD and CFIS) has been tested in the marine environment in spring and autumn. Concretely the study has been performed in Mar Menor Lagoon (SE of Iberian Peninsula, Spain), that is a hypersaline (42 to 47 psu) coastal lagoon with a mean depth between 3 and 4 m, that is one of the largest ones (135 km2) of the Mediterranean basin. Albujón Wadi is the main surface watercourse that flows into this lagoon from Cartagena Field, which is one of the most relevant horticulture areas in Europe. The samplers have been immersed in 4 sampling points for 1 week and the daily concentration of pollutants has been determined by SBSE/GC/MS. CFIS and SPMD systems are two useful tools as integrative samplers in the marine environment and results were similar to those obtained with daily sampling method. Their potential application is limited by the hydrofobicity of the considered pollutants, because they are not adequate for the more hydrophilic compounds as triazines.

### EC01B-6

**Evaluation of non agricultural pesticides air contamination: a field study using Tenax passive samplers**

M Millet[1], CR Raeppel[1], BMR Appenzeller[2], OB Briand[3], LT Tuduri[4]
[1]University of Strasbourg / CNRS, STRASBOURG CEDEX, France
[2]CRP-Santé / Université du Luxembourg, LUXEMBOURG, Luxembourg
[3]ANSES, MAISONS-ALFORT, France
[4]EPTC-Université de Bordeaux1 / CNRS, BORDEAUX, France

Pesticides are not only used in agricultural activities, they are also used for different treatments like pest control or green way and public roads upkeep. To evaluate the influence of these latter activities on air contamination, the technique of passive air sampling has been chosen. This simple method is easy to carry out and cost-efficient, and it allows large scale sampling, essential for providing a specific description of the spatial and temporal variations in the atmospheric contamination levels. The passive air samplers (PAS) used in this study have been developed in our laboratory and consist of a Tenax resin tube protected by a specially designed shelter allowing an air flow. This system enables diffusion through the Tenax resin tube. Afterwards exposure, the tubes have been extracted by thermal desorption using an Automatic Thermal Desorber (ATD). After this first step, molecules have been analysed by gas chromatography and mass spectrometry. In this study, two sites of two companies and one of a private house located in eastern France were chosen to perform the sampling which occurred after a professional or non-professional pesticides application for the upkeep of the areas. In total, eight active substances (2,4 D, Dichlorprop, Diflufenican, Flazasulfuron, MCPA, Mecoprop-p, Picloram and Triclopyr) were used during the treatments and were therefore analysed. PAS were deployed outside but also inside, in the offices or in the house, in order to see if there is a possible contamination coming from outdoors. Results have showed that a part of applied pesticides were found mainly in the PAS corresponding to the day of the treatment. For example, following a treatment using 3 active substances, one pesticide was found, only outside, on the PAS put in place on the application day (Picloram: 1518 - 14326 pg.PAS-1.day-1). The second one was also detected on the treatment day but on following days too (Diflufenican: 1274 - 42941 pg.PAS-1.day-1), suggesting volatilisation process. 2,4 D was observed throughout the sampling, outside and inside (2,4 D: 200 - 19498 pg.PAS-1.day-1. This pesticide was also found in a blank made before the treatment what could be explained by another source, knowing that the sampling site is located in an agricultural area. But the highest values were nevertheless observed on the treatment day.

### EC01C-1

**Monitoring by LC-MS/MS of 28 endocrine disruptor compounds in surface water using passive sampling devices: comparison of POCIS and Chemcatcher**

J Camilleri[1], N Morin[2], C Cren-Olivé[1], M Coquery[2], M Miège[2]
[1]CNRS_SCA-USR59, SOLAIZE, France
[2]Cemagref, UR MALY, LYON, France

Regarding to the growth of interest concerning the presence and the identification of human made pollutants and xenobiotics in the environment, multi-residue analysis techniques and representative water sampling methods need to be developed. Some of these micro pollutants of interest are known as Endocrine Disruptor Compounds (EDCs) due to their effects on the endocrine causing behavior disorders, decreased reproduction or birth malformations for example. As those molecules display large range of physico-chemical properties, most of the current studies are focused on one or two EDCs families.

This project is focused on the evaluation of the current pollution of surface water media threw the development of a multi-residue and multi-family of EDCs analysis method coupled to passive sampling devices.

28 EDCs of interest have been selected for this project among emerging contaminants listed by the European Union. This combination of different EDCs families representating agricultural, pharmaceutical and human pollution, has been chosen to be found in surface water and analysed by liquid chromatography tandem mass spectrometry (LC-MS/MS).

Two passive sampling devices have been selected to monitor those compounds: the Polar Organic Chemical Integrative Samplers (POCIS in Pharm configuration) and the Chemcatcher (in polar configuration). Both are still in development but already showed good efficiency to monitor some of the compounds of interest. Calibration of those systems have been realised with the Cemagref Lyon in 50L aquariums with continuous renewal of doped solutions for 28 days. Both showed good linearity for most of the compounds of interest up to 21 or 28 days but seem to have reached equilibrium after 14 days for some of the molecules. Calibration experiment has been validated by Cemagref Lyon with controled and stable temperature, conductivity and flow. Both systems showed same behaviour but calculated sampling rates were higher for the POCIS than for the Chemcatcher. The two systems have been exposed in the field for 4 weeks between june and july 2010.

Experiments confirmed linearity for somme of the molecules and enable us to calculate sampling rates for some that hasn't been tested yet. Those two passive samplers combined to an optimised multi-residue analytical method allow us to monitor a representative mixture of endocrine disruptors in surface waters.

**EC01C-2**

**Calibrating passive sampling and passive dosing techniques to lipid based concentrations**

P Mayer[1], SN Schmidt[1], A Annika[2], MS Mclachlan[2], K Mäenpää[3], MT Leppänen[3]
[1]Aarhus University, ROSKILDE, Denmark
[2]ITM, Stockholm University, STOCKHOLM, Sweden
[3]University of Eastern Finland, JOENSUU, Finland

Equilibrium sampling into various formats of the silicone polydimethylsiloxane (PDMS) is increasingly used to measure the exposure of hydrophobic organic chemicals in environmental matrices, and passive dosing from silicone is increasingly used to control and maintain their exposure in laboratory experiments. Both these equilibrium partitioning approaches are normally calibrated to freely dissolved aqueous concentrations ($C_{free}$), which often are considered the effective concentration for partitioning, bioconcentration and toxicity. In the present studies we extend the calibration of such methods towards equilibrium partitioning concentrations in lipids ($C_{lipid,partitioning}$). The first approach proceeds in two steps; (i) the concentration in the PDMS ($C_{PDMS}$) is determined and (ii) multiplied with recently determined lipid to PDMS partition ratios ($K_{lipid,PDMS}$). The second approach applies external partitioning standards in vegetable or fish oil for the complete calibration of equilibrium sampling techniques without additional steps.

**Equilibrium in tissue sampling** in three different fish yielded lipid based PCB concentrations in good agreement with those determined using total extraction and lipid normalization. These results support the validity of the in tissue sampling technique, while at the same time confirming that the fugacity capacity of these lipid-rich fish tissues for PCBs was dominated by the lipid fraction.

**Equilibrium sampling of PCB contaminated lake sediments** with PDMS coated vials and with Head Space Solid Phase Microextraction (HS-SPME) yielded lipid based concentrations that were in good agreement with each other, but about a factor of two higher than measured lipid-normalized concentrations in the organisms.

**Passive dosing** was applied to bioconcentration and toxicity studies of several PAHs with the terrestrial springtail *Folsomia candida*. Within the bioconcentration study, equilibrium partitioning concentrations in lipids served as a well defined reference for the evaluation of measured concentrations in the springtails. In the toxicity tests of naphthalene, phenanthrene and pyrene, lethal concentrations were determined also on a $C_{lipid,partitioning}$ basis and were in good agreement with the typical range of lipid membrane burdens for baseline toxicity (40-160 mM). This demonstrates that these new calibration principles also can be applied within a toxicological context.

**EC01C-3**

**PWSDs-YES application as estrogenic chemicals screening and monitoring tool for STP effluents**

UJ Kim[1], Hy Kim[1], IS Lee[2], JE Oh[1]
[1]Pusan National University, BUSAN, South-Korea
[2]National Fisheries Research & Development Institute (NFRDI), BUSAN, South-Korea

Commonly, STPs are regarded as point source of the EDCs in water that have inhibited human and animal endocrine activities [1]. Conventionally to monitor these compounds in water from point source, grab water sampling was used to analyze pollutants but by this method, only water soluble compounds' temporal level can be detected and long term effect caused by bioaccumulation cannot be predicted [2]. It is suggested that integrative passive water sampling devices (PWSDs) like semi permeable membrane device (SPMD) can detect organic compounds in water to monitor wide concentration variation with time and to conjecture bioaccumulation of organic pollutants for a longer period [3]. Also, with combining yeast estrogen screening (YES), SPMD can show estrogenicity of sample as a term of Estradiol equivalent quantity (EEQ) [2]. Passive samplers have been used globally as monitoring tool for organic contaminants in water [4] but in Korea, grab sampling method is only used. With the restoration project on four major Korean rivers these days, water quality, flood control, and ecosystem vitality are major issues in Korea. Therefore, improvement of current water monitoring system is needed to understand correct status of water quality and potential impacts to the ecosystem. The research goal of this study is to develop water quality monitoring system using SPMD-YES combining method for monitoring Korean waters to compensate limitations of current water grab sampling methodologies. As a preliminary study, in this paper, comparison between grab and passive sampling was conducted for estrogenic compounds to check possibility of SPMD-YES application on water quility monitoring. Also several sophisicated conditions including adsorbent type, deployment period were tested.

Summary

Micro-algae as primary producers at the basis of the marine food chain are expected to be affected by anthropogenic contaminants and natural toxins in estuarine and coastal ecosystems. These chemical stressors are hypothesized to disturb algal growth and, therefore, the carrying capacity and sustainable development of estuarine and coastal ecosystems. In our study we aim to identify the chemical compounds that have an effect on algae in order to quantify the toxic pressures in the Dutch coastal zone.

In the present study, passive sampling of dissolved chemicals is performed and different extraction methods are tested in order to find a suitable method for further research with effect-directed analysis (EDA) to identify chemical compounds that affect algal life. Pulse amplitude modulated fluorescence (PAM) was used to test algae toxicity of concentrated samples and fractions thereof. We have compared different extraction methods that are suitable for the concentration of a broad range of compounds from marine water in order to identify unknown toxic compounds. Different passive samplers were compared with water extraction methods in terms of performance and response in the PAM assay.

Passive samplers seem to provide i) an increase in method sensitivity, ii) simplicity in use, and iii) relevance to ecological risk assessments not easily obtainable with extraction of water samples.

Acknowledgement - This project is financed by DELTARES, NL.

**EC01C-5**

**Sorption and desorption kinetics of polar organic chemicals on Empore disks deployed in the passive sampler Chemcatcher**

ELM Vermeirssen[1], C Dietschweiler[1], BI Escher[2], J van der Voet[1], J Hollender[1]
[1]Eawag, DÜBENDORF, Switzerland
[2]National Research Centre for Environmental Toxicology (Entox), BRISBANE, Australia

Sorption and desorption kinetics of 22 compounds were investigated with Empore disks as a receiving phase. The polymer used was poly(styrenedivinylbenzene) modified with sulfonic acid groups to make it more hydrophilic: SDB-RPS. The octanol water partitioning coefficients ($logK_{ow}$) of the compounds ranged between -2 and 4. Three sorption studies were performed to determine the partitioning coefficients between SDB-RPS and water ($K_{SDB-water}$), sampling rates ($R_S$), and the time needed for compounds to reach half the equilibrium state ($t_{½}$; a measure of integrative sampling capacity). The sorption experiments were performed in a channel with flowing river water (8 cm/s; ca. 15 °C) that was spiked with the set of 22 compounds to reach aqueous concentrations between 400 and 1000 ng/L. SDB-RPS disks were placed in a modified (rectangular) version of the Chemcatcher disk holder and positioned uniformly at the sides of the channel. Duplicate disks were removed over periods of 6 to 12 days and extracts analysed with LC-MS/MS. Also desorption of chemicals from SDB-RPS was studied in the channel. Disks were placed in the channel with spiked river water to passively load them with the compounds. Then, the channel was drained and refilled with unspiked river water and desorption was followed by removing duplicate disks over 12 days. In another experiment, passively loaded disks were placed in beakers filled with tap water. Thus the proportion of desorbed compounds (over 12 days) could be assessed by measuring both the disk and the water phase. In a third desorption experiment, passive loaded disk were placed in a circular tank with a flow through of deionised water, to maintain aqueous concentrations of desorbed compounds at 0. Sorption experiments produced fairly robust values of $K_{SDB-water}$, $R_S$ and $t_{½}$ (the CV of the parameters ranged between 11 and 21%). Values of all three parameters tended to increase with the hydrophobicity of the tested compounds. Sampling rates ranged between 0.1 and 0.4 L/d, and t½ was fairly low, between 2 and 6 days. All compounds readily desorbed from SDB-RPS. More hydrophilic compounds showed a higher proportion of compounds desorbing in the channel and the beaker (up to 70%) compared to the more hydrophobic compounds (up to 10% desorption). The percentage desorption correlated linearly with hydrophobicity. Desorption reached very high levels >90% in the flow through system running with deionised water.

**EC01C-6**

**Comparison of four passive samplers for the determination of anti-androgenic contaminants in surface waters**

C Liscio, A Abdul-Sada, EM Hill
University of Sussex, FALMER, United Kingdom

Endocrine disrupting compounds (EDCs) are environmental contaminants that have the potential to disrupt the normal functioning of the neuroendocrine system in humans and animals[1]. Endocrine disruption appears to be particularly prevalent in the aquatic environment,possibly because aquatic animals are highly susceptible to EDCs effects as long-life exposed through wastewater effluents. Thus far, endocrine disruption has been mostly concerned with estrogenic compounds but recent surveys have indicated antiandrogenic activity in aquatic environments[2]. It is therefore crucial to identify the currently unknown structures of antiandrogenic chemicals in effluents in order to determine their contribution to the reproductive dysfunction in aquatic populations and their potential risk to human health. Most conventional environmental screening methods in water involve grab sampling and only provide a snapshot of the levels of pollutants at the time of sampling. Passive sampling can be an alternative sampling approach that overcomes these limitations[3]. Since anti-androgenic compounds in effluents are a complex mixture of polar and apolar chemicals [4], passive samplers able to sample the broadest range of log Kow must be used. Passive samplers can usually be suitable for hydrophilic or for hydrophobic compounds[5]. In this study, 4 different passive samplers were investigated for their ability to extract a variety of hydrophilic and hydrophobic contaminants and detect anti-androgenic activity present in contaminated surface waters. Two single-phase passive samplers were preliminarily tested to check sampling efficiency, showing good recoveries for a wide range of compounds. An extraction method was optimized and passive sampler anti-androgenic activity was tested before and after membrane precleaning to evaluate background contribution. Deployed passive samplers showed significant differences in the anti-androgenic activity profiles. Current work is focusing on the identification of key antiandrogenic contaminants present in passive sampler extracts using bioassay-directed fractionation and mass spectrometry.

**Headspace POM-SPE as a novel and fast (48 h) passive sampling approach to determine PAH bioavailability in field sediments**

MTO Jonker, AR Breeveld
Institute for Risk Assessment Sciences, UTRECHT, The Netherlands

Bioavailability of hydrophobic organic contaminants (HOCs) in sediments and soils can be determined by measuring either the rapidly desorbing fraction (e.g., with Tenax or cyclodextrin) or the freely dissolved concentration in pore water (with passive samplers, such as SPME or POM-SPE). Recent comparison studies suggest that the second approach generally provides the most accurate assessments of uptake and subsequent effects of HOCs; however, the main disadvantages of passive samplers are that their application requires sampler-water partition coefficients and that equilibration takes several weeks. In terms of commercial applications, such long equilibration times are undesirable. The objective of the present study was therefore to develop a novel bioavailability method based on passive sampling, which should however yield results much faster than conventional passive sampling techniques. To this end, we applied headspace analysis with passive samplers at elevated temperatures. Focus was on polycyclic aromatic hydrocarbons (PAHs) in field-contaminated sediments. Out of 6 different headspace samplers, POM was selected as optimal phase, based on extracted PAH pattern and data variability. Optimal exposure conditions were obtained in stirred systems at 120 degrees Celcius. Under these conditions, equilibrium was reached in only 48 hours. The mass of sediment, water, and POM, as well as the length of the cool-down period appeared not to be crucial, which indicates a robust (not operationally-defined) method. In order to match PAH concentrations in POM upon extraction of sediments during headspace analysis to PAH concentrations accumulated in aquatic worms (Lumbriculus variegatus) during bioaccumulation experiments, a correction factor was required. The application of such a factor does not turn the method into an empirical one by definition; rather the factor reflects the interplay of the (unknown) bioaccumulation factors, Henry constants, and the POM-air partition coefficients at 120 degrees Celcius. Interestingly, the correction factor appeared independent of the PAH and the sediment. Its application resulted in a close relationship between measured and predicted PAH concentrations in worms (predictions within a factor of 5). Headspace POM-SPE therefore appears to be a simple, fast, and robust method to determine PAH bioavailability in sediments. Its advantages over conventional passive sampler use will be discussed.

**EC01D-2**

**Investigation of dioxin-like activity in water from the Three Gorges Reservoir**

KW Schramm
Helmholtz Zentrum München, NEUHERBERG, Germany

The Yangtze River is the third largest river in the world and the Three Gorges Dam (TGD) is the largest dam in the world. The closing of the TGD may result in drastic environmental alterations. Persistent organic pollutants (POPs) are ubiquitous environmental contaminants. Trace POPs in water of TGR were only reported sporadically, their ecotoxicological effects have never been studied there. EROD assay is generally regarded as being an early warning signal for the Ah-receptor-related toxic effects of PCBs, PAHs, and related compounds. EROD with H4IIE rat hepatoma cells bioassay is a bioassay established to measure CYP1A1 induction caused mostly by dioxin-like chemicals in environmental samples.
In this study, triolein SPMD technology was applied to sample and concentrate the priority organic pollutants in water of TGR. EROD-bioassay was used to assess the potential toxicological effects of water in TGR. The aim of this study was to investigate the levels and distribution patterns of Ah-agonists effects in surface water of TGR by combining SPMD sampling technology with EROD bioassay.
After 24 h incubation the TEQ value is related to all the compounds able to elicit a response (persistent and non-persistent compounds). Compounds that still elicit a response after 72 h incubation in the EROD bioassay are defined as persistent. EROD of 7 and 24 d exposure ranged from 27-990 pg TCDD/sample. However, the TEQ of PCB only ranged from 0.04-2.5 pg TCDD/sample. Therefore, PCB contributes very little to the EROD activity in the samples from water of TGR. The TEQ of PAH ranged from 6.4-42.3 ng TCDD/sample. Therefore, PAH in SPMD may be main contributor to EROD activity of 24 h incubation. In case of 72 h incubation, other persistent compounds not targeted in the study may exist to cause EROD induction. Further study warranted to clarify the differences.

**EC01D-3**

**Determination of high partition coefficients from diffusive mass transfer in the boundary layer**

JH Kwon[1], H Lee[1], HJ Kim[1], Y Ha[1], BI Escher[2]
[1]Ajou University, SUWON, South-Korea
[2]University of Queensland, BRISBANE, Australia

In many areas of environmental sciences and engineering, partition coefficients (K) are widely used for the characterization of the fate of chemicals. Experimental determination of partition coefficients between two phases, however, becomes very difficult as the absolute value increases. In a conventional shaking method, time required for equilibration between two phases increases exponentially with increasing log K. This often results in many potential experimental artefacts. Thus, an innovative method using the diffusion in the boundary layer has been developed to measure partition coefficients between two phases. According to a film diffusion theory in the boundary layer, the rate of diffusive mass transfer is a function of diffusion coefficient, the thickness of the boundary layer of a fluidic medium, and partition coefficient between the two phases. Partition coefficient can be correlated with experimentally determined mass transfer coefficient by a simple relationship because diffusion coefficients in a well-characterized medium such as air and water can be easily predicted and the thickness of the boundary layer is a dynamic property of the medium. This principle is substantiated in three model systems - partition coefficients between poly(dimethylsiloxane) and water ($K_{PDMSw}$), 1-octanol/air partition coefficient ($K_{oa}$), and Henry's law constant (H). Kinetically measured partition coefficients were well correlated with literature data without only a few chemicals. The range of partition coefficients that can be determined within 30 h was $10^3$~$10^6$ for $K_{PDMSw}$, $10^5$~$10^{10}$ for $K_{oa}$, and $10^{-4}$~$10^{-7}$ atm m$^3$ mol$^{-1}$ for H.

**EC01D-4**

**Does the kinetic resistance on the sampling medium side affect passive air sampling rates? Experimental evidence and modeling.**

X Zhang[1], Y Lei[1], F Wania[1], M Tsurukawa[2], T Nakano[2]
[1]University of Toronto, TORONTO, Canada
[2]Hyogo Prefectural Institute of Environmental Sciences, KOBE, Japan

The mechanism of passive air samplers (PASs) is based on molecular diffusion from air to the passive sampling medium (PSM). According to the curret model for the PAS, the kinetic resistance for the chemical transfer is mainly contributed by the boundary layer between air and PSM. Within the PSM, the chemical is assumed to distribute uniformly and the kinetic resistance is negliable. The air concentration (ng/m$^3$) can be derived from the sequestered chemical amount ($m_s$, ng) and the passive sampling rate ($R$, m$^3$/d). At the initial uptake stage, when surface evaportation is negliable, mS linearly increases with the PAS deployment time and R is proportional to the chemical's molecular diffusivity in the air, which is a weak function of temperature and molecular size. However, recent field calibration studies on PAS observed a larger variations of *R* on temperature and molecular size than can be explained with the model. In this study, we developed a hypothesis that the chemical sequestered on the PSM is not uniformly distributed. To test the hypothesis, uptake kinetics within PSM was investigated by using cylindrical XAD- (and PUF-)PSM concentrically segmented into three layers. PCBs uptake kinitics on each of the layers were measured in duplicates at seven time points from 1 (0.5) week to 24 (12) weeks. Results indicate PCBs sequestered are non-uniformly distributed within the PSM. Even for the mono- and di-PCBs which are more volatile (lower sampling medium-air partitioning coefficient), over 80% distributed in the outter layer of the PSM. Based on the experimental results, a model considering the chemical transfer and kinetic resistance within the sampling media was developed to describe the passive sampling process.

**EC01D-5**

**Sorption behaviour of polar organic compounds on passive sampling material - Which functional group governs sorption?**

PS Bäuerlein, J Mansell, TL ter Laak, P de Voogt
KWR, NIEUWEGEIN, The Netherlands

Pharmaceuticals are expected to become a growing problem.[1] Very often, these compounds can be found in waste water, or enter directly in the environment. In general, they are polar or even charged molecules and their concentration are low, which makes their detection often very difficult. Concentration of these compounds with passive sampling is promising way to allow for the analysis with standard techniques such as MS. Many materials have been employed for this purpose,[2-4] but not much is known about the exact sorption mechanism of the compounds on these materials.
Aim of the research is to get a better insight into the influence of various functional groups in selected chemicals on the sorption to frequently employed passive sampling materials. Therefore, we decided to employ the commonly used OASIS polymers (HLB, WCX, WAX, MAX and MCX). These polymers carry a-polar moieties, hydrophilic part as well as charged groups, which should allow the adsorption of the target compounds. Various polar chemicals were tested on the different OASIS polymers to determine which functional group in the compound is crucial for a successful sorption on the OASIS material. This knowledge is crucial to taking a grounded decision which sorbent can be employed as a passive sampling material.
The results of this research indicate that especially apolar functionalities have a great impact on the sorption, whether the compound is charged or not. The more pronounced the apolar moiety is, the better the compound can interact with the sorption material. Furthermore, it emerged that the conditions of the aqueous phase, such as salt concentration, influence the sorption behaviour of charged molecules dramatically. The higher the salt concentration the lower the adsorption of charged compounds, hence the Kd values.

**Application of passive dosing to study the biotransformation and biodegradation of hydrophobic compounds**

EC Smith[1], A Rein[2], S Trapp[2], MB Heringa[3], P Mayer[1], U Gosewinkel Karlson[1]
[1]National Environmental Research Institute, ROSKILDE, Denmark
[2]Technical University of Denmark, LYNGBY, Denmark
[3]KWR, Watercycle Research Institute, NIEUWEGEIN, The Netherlands

Achieving well-defined and constant dissolved concentrations of hydrophobic compounds is challenging due to volatilization or sorptive losses. With passive dosing, continual partitioning into the test medium of compound(s) loaded in a polymer compensates for losses, and provides defined and constant dissolved concentrations. Passive dosing can be used for studying biotransformation/degradation. Here, the polymer HOC reservoir also compensates for losses due to the bio-transformation/degradation process itself. Furthermore, a large mass of test compound is introduced so that compound turnover is significant even at low dissolved concentrations thus facilitating measurement of the relevant endpoint (e.g., metabolic products in biotransformation or growth in biodegradation). This study details two applications of passive dosing for studying bio-transformation/degradation. A format has been developed to study the biodegradation of phenanthrene and fluoranthene by the bacterial strain EPA 505, allowing degradation rates to be quantified at defined freely dissolved concentrations from mg/L down to ng/L levels. Passive dosing was also applied for quantifying the mutagenicity of benzo(a)pyrene metabolites produced after activation by the liver S9 mix in the in vitro Ames II assay. Compared to the case with spiking, responses from passive dosing were shifted by a factor 100-1000 to lower concentrations, and were also more reproducible between repeated tests. This difference in apparent sensitivity cannot solely be explained by partitioning, and is due to slow dissolution kinetics as well as mass-depletion of the spiked benzo(a)pyrene. Therefore, passive dosing is a useful tool for the study of hydrophobic compound bio-transformation/degradation at well-defined dissolved concentrations down to very low levels. Important advantages include studying process kinetics at precisely defined dissolved concentrations and allowing increased compound turnover even at constant and low concentrations.

## EC02 - Atmospheric chemistry, transport and deposition

**EC02A-1**

**The global fate and transport of organic contaminants: concepts and misconceptions**

F Wania[1], D Mackay[2]
[1]University of Toronto Scarborough, TORONTO, Canada
[2]Trent University, PETERBOROUGH, Canada

Following the detection of synthetic organic chemicals in remote and sparsely populated regions of the global environment in the 1960s, there has been a steady increase in the understanding of the processes that control a chemical's spatial range in the environment. Measurements of the occurrence of contaminants in remote environments have been complemented with conceptual and numerical models of varying complexity that seek to explain, quantify, and predict a chemical's ability to undergo long range transport and to accumulate in remote regions. In particular, the concepts of global fractionation and global distillation that we formulated in two papers in the mid-1990s have captured the imagination of many with a concern for the global fate and transport of organic contaminants. While reviewing the literature we frequently encounter misconceptions, especially surrounding the use of terms such as the global chromatography, global fractionation and distillation, grass-hopping, and cold condensation. We have encountered a number of misconceptions, such as "cold condensation results in the precipitation of pure chemical", "the bulk of a persistent organic contaminant's global inventory will eventually migrate to reach the poles", "global fractionation is driven by temperature gradients"or "low temperatures will cause higher concentrations in air". It is perhaps inevitable that misconceptions arise because the phenomena are complex and there is often a lack of reliable emission, monitoring and physical chemical property data. In this presentation we describe and discuss the concepts or present state of the science surrounding global transport of chemicals, especially over considerable latitudinal differences with their inevitable differences in temperature.

**EC02A-2**

**Global cycling of PCBs - intercontinental and northward migration of distributions predicted by multicompartmental modelling**

I Stemmler, GL Lammel
Max Planck Institute for Chemistry, MAINZ, Germany

Global distribution and fate of contaminants depend on physical-chemical properties, geo-spheric transports, effectiveness of exchange between the atmosphere and ground compartments and degradation kinetics. A comprehensive global multicompartmental model (MPI-MCTM, [1]) is used to study how substance properties together with environmental conditions propagate into PCBs global distributions. This is the first time a fully coupled global atmosphere ocean general circulation model is used for studying PCBs. A special focus is given to intercontinental transport To discern the impact of the substances physico-chemical properties on fate, identical primary emissions (i.e. PCB 153 emissions were input to study four PCB congeners, i.e. 28, 101, 153, and 180. The period 1950-1995 was simulated under present-day model-generated climate with spatial resolutions of 3.75° (T31) in the atmosphere and approx. 3° (GR30) in the ocean. The substance large-scale mobility in meridional direction is compared with the predictions of a global, zonally averaging model, GloboPOP [2], run with similar input parameters (emissions, besides others).

The centre of gravity (COG) of soil and vegetation burdens shows a different migration pattern for Eurasia and North America and amongst the PCB congeners. Whereas for Eurasia the migration is following the main wind direction (westerlies), for North America the formation of a secondary burden maximum in Alaska shifts the COGs to the northwest. This secondary maximum was found to be caused by trans-Pacifc transport of PCBs, rather than local emissions. Trans-Pacfic transport of PCBs is shown to be related to an amplified wave pattern in the North Pacific region, with a lower than usual Aleutian Low and higher than usual surface layer pressure over the north American continent leading to events of effective transport.

The results proof that atmospheric transport is very effective for large-scale re-distribution of PCBs. The meridional re-distribution is more effective, but relaxes slower to long-term changes in emissions than predicted by a zonally averaging model. On the decadal time scale trans-Pacific transport constitutes a significant secondary PCB source to North America.

**EC02A-3**

**Can clouds enhance long-range transport of low volatile, ionizable and surface-active chemicals?**

A Franco, S Trapp
Technical University of Denmark, KGS. LYNGBY, Denmark

Atmospheric partitioning and transport of low volatile organic compounds is strongly influenced by the presence of water (e.g. clouds) and its deposition velocity (e.g. rainfall, snow). It was identified that the assumption of continuous rainfall underestimates the residence time and the transport potential of non-volatile substances. The liquid water content of clouds and the high specific surface of frozen or liquid cloud droplets can significantly contribute to the total activity capacity (i.e. the capacity to sorb chemicals) of the atmosphere for non-volatile, ionizable and surface active substances.

A modified version of the regional multimedia activity model for ionics MAMI, including two-layered atmosphere with atmospheric boundary layer (ABL) and lower/middle troposphere (LMT), interface partitioning, intermittent rainfall and variable cloud coverage was applied to a selection of ten low volatile or ionizable chemicals to investigate the potential of clouds to enhance the atmospheric transport potential.

Probability density functions were derived for input substance properties and environmental parameters to quantify uncertainty and variability and probabilistic simulations at steady state were run for a constant emission to the atmospheric boundary layer to identify key model inputs.

The degradation rate, the duration of dry and wet periods and the parameters describing air-water bulk partitioning ($K_{AW}$ and T) and ionization (p$K_a$ and pH) determine the residence time in the ABL. In the LMT, however, the residence time depends also on the water content of clouds and on interface partitioning. In some cases the residence time and its variability range is similar in the two compartments, while some compounds (e.g. diazinon, 2,4-D, perfluorooctanoic acid) are more persistent in the LMT. The longer residence time predicted for some compounds in the LMT is due to the capacity of clouds to sorb non-volatile molecules in the liquid water and at the interface of cloud droplets.

The efficiency of wet deposition to remove low volatile organic pollutants from the atmosphere is limited primarily by the duration of the dry interval between precipitation events. During dry periods persistent non-volatile chemicals can be transported to the troposphere. Here, the high capacity of of tropospheric clouds to sorb non-volatile and surface active chemicals limits oxidation and wet deposition rates and increases the potential for long-range transport

**EC02A-4**

**Organic tracer compounds of ambient air particulate matter in the Western Mediterranean Basin and influence of natural and anthropogenic emission sources**

BL van Drooge[1], J Lopez[2], M Aceves[3], X Querol[2], JO Grimalt[2]
[1]Institute of Environmental Assessment and Water Research, BARCELONA, Spain
[2]IDAEA-CSIC, BARCELONA, Spain
[3]EMA Air Quality and Mobility, BARCELONA, Spain

Monitoring and chemical analysis of atmospheric particulate matter (PM) is important due to its health impact and influence on climate change (1,2). The air quality in the urban area of Barcelona in the Western Mediterranean Basin is dominated by traffic related emissions and characterized by high levels of particulate matter and reactive chemical species due to emissions, the weak synoptic conditions and high solar radiation (3,4). Nevertheless, occasionally emissions from natural sources, such Saharan dust from Northern Africa and wildfires on the Iberian Peninsula, substantially influence the levels of the PM (5). Selected filter samples from 2009, representing different 'scenarios', were analyzed on organic tracer compounds, e.g. polycyclic aromatic hydrocarbons, hopanes, alkanes, anhydrosugars and primary sugars, as well as secondary organic aerosols tracer compounds, e.g. carboxylic acids. The results are discussed in terms of their relation to emission sources and influence of meteorological conditions in order to get an insight on the complex organic aerosol.

**Sources, Transport and Deposition of Polycyclic Aromatic Hydrocarbons: China and the Western U.S.**

SL Simonich
Oregon State University, CORVALLIS, United States of America

Polycyclic aromatic hydrocarbons (PAHs) emissions have been increasing in parts of Asia due to increased combustion and China is now the world's largest emitter of PAHs. Size fractionated particulate matter (PM) samples (including PM2.5 and PM10) were collected in Beijing before, during and after the 2008 Olympics, during both source control and non-source control periods, and analyzed for a wide range of PAHs, nitro-PAHs, oxy-PAHs, and high molecular weight (MW 302) PAHs. These data were used to understand the effect of source control measures on reducing PAH concentrations in a Chinese megacity. In addition, using a series of remote sites located at different elevations in the Pacific Northwestern U.S., the episodic atmospheric transport of PAHs from Asia to the U.S. west coast was identified. The deposition and accumulation of PAHs was also studied at remote, high elevation sites in western U.S. national parks. PAH sources to these remote ecosystems included local aluminium smelting activities, urban areas, and natural gas flaring.

**EC02A-6**

**Contaminant profiles of air and soil around Casey station, Antarctica; discerning local and distant contaminant sources**

M Bengtson Nash[1], H Xiao[2], M Schlabach[3], C King[4], JS Stark[4], H Hung[2]
[1]Griffith University, BRISBANE, Australia
[2]Environment Canada, TORONTO, Canada
[3]Norwegian Institute for Air Research (NILU), KJELLER, Norway
[4]Australian Antarctic Division (AAD), HOBART, Australia

The primary input of Persistent Organic Pollutant (POP) contamination to the Antarctic is expected to be via Long Range Atmospheric Transport (LRAT) from emissions in neighboring Southern hemisphere nations. In addition to LRAT, system input of POPs must increasingly consider alternate pathways. Human activity in the Antarctic represents a potential direct source of both legacy and current-use chemicals.

It has been two decades since the organic chemical composition of air masses arriving in the Australian Antarctic Territory (AAT), which spans the majority of the eastern Antarctic sector, was last investigated. Here we present the first atmospheric measurements made as part of a new continuous monitoring effort at Casey station (66°17' S 110°31' E), one of Australia's all-year research stations. The results are evaluated alongside POP contamination data of soil samples collected around the Casey station perimeter and the respective sample profiles are assessed for clues as to local and distant contamination sources.

Results suggest a potential local source of the currently produced, involatile, deca-brominated PBDE congener 209 which contributed substantially to PBDE profiles of all samples. Profiles of polychlorinated biphenyls (PCBs) and organochlorine pesticides on the other hand primarily support LRAT as the primary input pathway of these contaminants, whilst a dominance of endosulfan in air samples evidences its ongoing application in the southern hemisphere.

**EC02B-1**

**A trace element approach for determining the geographic sources of semi-volatile organic contaminants in an alpine ecosystem in New Zealand**

KS Lavin[1], KJ Hageman[1], SK Marx[2], BS Kamber[3], PW Dillingham[1]
[1]University of Otago, DUNEDIN, New Zealand
[2]University of Queensland, BRISBANE, Australia
[3]Laurentian Unviersity, SUDBURY, Canada

Semi-volatile organic contaminants (SOCs) are known to be transported thousands of kilometres in the atmosphere. Ultimately, these SOCs end up in cold remote ecosystems far from where they have been used. The transport mechanism of SOCs to these pristine locations occurs via a series of volatilisation-transport-condensation steps, however little is known about the SOC contribution of different geographic sources to a specific remote site. Previous studies have used local wind observations and/or air-mass back-trajectory modelling to gain information about the geographic sources of SOCs to remote sites. However, these modelling-type approaches have limitations. Local wind observations can be highly variable, especially in complex mountainous terrain, and do not adequately describe long-range sources. On the other hand air-mass back-trajectories tend to ignore localised synoptic-scale winds in an alpine area in favour of global-scale winds. The objective of this study was to investigate a new geographic source apportionment method for SOCs that uses trace element profiles in atmospheric particulate matter (PM) to determine SOC origin. Daily samples of PM and SOCs were simultaneously collected using two high-volume air samplers from 16 January to 16 February 2009 at Temple Basin, a remote alpine ecosystem in New Zealand's Southern Alps. For each sample day, the relative contribution of regional New Zealand sources versus longer-range Australian sources was determined using a binary mixing model of the source trace element profiles. In addition, local wind observations were used to determine the percent of time the wind came from each source region, while HYSPLIT air-mass back-trajectory modelling was used to determine the percent of time the air mass had spent in each source region before reaching the sampling site. The trace element, local wind observation and air-mass back-trajectory approaches were used in correlation analysis with SOC concentrations. Correlation analysis indicated that the organochlorine insecticide endosulfan I tends to be transported from Australia, while the broad-spectrum organophosphate insecticide chlorpyrifos is largely influenced by regional transport from the agriculturally-rich Canterbury Plains of New Zealand. In addition, the high molecular mass polycyclic aromatic hydrocarbons (PAHs) tend to come from longer-range Australian sources, while the low molecular mass PAHs tend to come from more localised New Zealand sources.

**EC02B-2**

**Comparison of lichen, conifer needles, passive air sampling devices, and snowpack as passive sampling media to measure semi-organic volatile organic compounds in the atmosphere**

JE Schrlau[1], L Geiser[2], KJ Hageman[3], D Landers[4], SM Simonich[1]
[1]Oregon State University, CORVALLIS, United States of America
[2]USDA Forest Service, CORVALLIS, United States of America
[3]University of Otago, DUNEDIN, New Zealand
[4]4Environmental Protection Agency-Western Ecology Divison, CORVALLIS, United States of America

Passive sampling media, including lichen, two-year old conifer needles, resin-based passive air sampling devices (PASDs), and snowpack were used to monitor semi-volatile organic compounds (SOCs) in the atmosphere at pristine, high elevation sites in western United States national parks. The magnitude of accumulation and relative sorption affinities for SOCs were compared in all four sampling media to determine the affect of media properties and SOC physical chemical properties on accumulation. Lichen and two-year old conifer needles preferentially accumulated endosulfan sulphate, PASDs preferentially accumulated HCB, and snowpack preferentially accumulated dacthal, pyrene, benzo[a]anthrancene, benzo[b]fluoranthene, benzo[k]fluoranthene, indeno[1,2,3-cd]perylene, dibenzo[ah]anthracene, and benzo[ghi]perylene. Regression analysis confirmed snowpack and lichen showed a similar composition of the atmosphere compared to conifer needles and PASDs. The influence of air-water partition coefficient ($K_{AW}$) , log octanol-air partition coefficient (log $K_{OA}$) , and the estimated SOC fraction in the particulate phase (Φ) on accumulation was evaluated. All four passive sampling media accumulated more SOCs with $K_{AW}$ values up to 0.05, log $K_{OA}$ values between 8 and 10, and Φ up to 20. Of the total measurements made for lichens, conifer needles, PASDs, and snowpack, 4, 0.7, 0, and 22% corresponded to SOCs with Φ > 60% indicating lichen and snowpack had a greater affinity for particulate phase SOCs compared to conifer needles and PASDs.

**EC02B-3**

**Influence of the longe-range transport of POPs in the Antarctic ecosystem**

A Cabrerizo[1], J Dachs[1], H Garrido[2], MJ Ojeda[1], D Damià[1], KC Jones[3]
[1]Institute of Environmental Assessment and Water Research (IDAEA-CSIC), BARCELONA, Spain
[2]Estación Biológica de Doñana-CSIC, SEVILLA, Spain
[3]Lancaster environmental Center (Lancaster University), LANCASTER, United Kingdom

Polar territories play a very significant role in global environmental processes as they can give useful information about the influence of long-range transport processes, compound partitioning and fate processes. The most significant findings on the presence of persistent organic pollutants (POPs) in the terrestrial ecosystem of Deception, Livingstone Island and Byers Peninsula (Antarctica) are presented. Soil and antarctic vegetation (liquens and mosses, which in fact are important bioindicators of atmospheric pollutants deposited by wet or dry deposition), samples were collected in many sampling sites located in the large area of the Islands during a Spanish expedition in the Antarctica (Jan-Feb 2009) within the ATOS project. Air samples were also collected with active samplers deployed in 3 different altitudinal sites of Livingstone Island (from the Spanish Juan Carlos I research facility to the glacier). Only low-medium MW PAHs and medium chlorinated PCBs and HCB were detected in most soils, vegetation and air samples, with exception of those samples taken close to the research facility, in which the higher MW PAHs were also detected. This finding highlights the importance of the long-range transport of POPs to the pristine ecosystems. Higher POPs concentrations were also detected in soils of penguins colonies, suggesting that apart of long range transport of POPs, antarctic penguins may also redistribute POPs at local scale.

**EC02B-4**

**Polycyclic aromatic hydrocarbons in air over Central Europe: what can we learn from diagnostic ratios for source apportionment and reactivity?**

A Dvorska, G Lammel, J Klánová, K Hošková
Research Centre for Toxic Compounds in the Environment, BRNO, Czech Republic

Despite numerous uncertainties, diagnostic ratios (DRs) of parent polycyclic aromatic hydrocarbons (PAHs) are frequently used for source apportionment of these pollutants. However, due to the simplicity of the method, it is attractive especially for countries, where (e.g. due to lack of measurement data) sophisticated source apportionment methods cannot be applied.

The following five commonly used PAH DRs were investigated: anthracene / (anthracene + phenanthrene) ANT/(ANT+PHE), fluoranthene / (fluoranthene + pyrene) FLT/(FLT+PYR), benzo(a)anthracene / (benzo(a)anthracene + chrysene) BAA/(BAA+CHR), indeno(123cd) pyrene / (indeno(123cd)pyrene + benzo(ghi)perylene) IPY/(IPY+BPE) and retene / (retene + chrysene) RET/(RET+CHR).

PAH DR values derived from a literature survey on suitable PAH emission factors were applied to study their ability to distinguish between PAH sources at sites with well described source categories (road traffic, residential heating, industry) in the Czech Republic, Serbia and Bosnia and Hercegovina. Later, seasonal changes in source characteristics at the background receptor site Košetice, Czech Republic, were examined using ambient PAH data from long term monitoring (1996-2008). Then a mass balance model of PAHs in air was applied and uncertainties of PAH reaction rate coefficients were narrowed down. The suitability of PAH DRs for distinguishing between various characters of sampling sites (urban, industrial, rural, background) in regions with very limited information on ambient PAHs (15 countries in Africa) was also studied using data from a passive air sampling campaign conducted in 2008.

A good agreement between some literature based PAH DRs and ambient DRs from sites with a dominant influence of a local source was observed. However, the current knowledge on PAH reactivity was found to be insufficient for source apportionment of atmospheric PAHs at receptor sites far from sources. DRs were used to narrow down ozone and OH radical reaction rate coefficients´ uncertainties: kO3(2) of PYR and BPE in the particulate phase seem to be _10% of the highest rate coefficient measured using model aerosols in the laboratory and kO3(2) IPY in the gas phase could be higher than previously estimated by three orders of magnitude.

**EC02B-5**

**Background atmospheric concentrations of PAHs are controlled by ubiquitous emissions from soils**

A Cabrerizo[1], J Dachs[1], C Moeckel[2], MJ Ojeda[1], G Caballero[1], D Damià[1], KC Jones[3]
[1]Institute of Environmental Assessment and Water Research (IDAEA-CSIC), BARCELONA, Spain
[2]Lancaster Environmental Center (Lancaster University), LANCASTER, United Kingdom
[3]Lancaster environmental Center (Lancaster University), LANCASTER, United Kingdom

Soils are the major reservoir and one of the major sinks for POPs due to their strong affinity to soil organic matter (SOM). The fate and toxic effects of POPs are strongly affected by the quality and quantity of SOM which controls POPs availability for biological degradation, burial or re-volatilization from soil. The main objectives of this study are to i) study the temporal and spatial variability of soil PAH fugacity and soil-air partition coefficients in rural and semi-rural areas of the Ebro river basin (Spain), NW England and urban Barcelona; ii) determine the soil/air fugacity quotients and the variables affecting them, in different soil types, under field conditions; iii) consider the field evidence for possible in-situ production of lighter PAHs in temperate areas to improve the understanding of PAH cycling and their implications as soil emissions controlling atmospheric concentrations of PAHs. Large soil fugacities were found compared to ambient air fugacities for PAHs with 2-3 aromatic rings and their alkyl derivatives at all the sites. The values of fs/fa were larger in early and late summer than in early winter. Daily ln (fs/fa) for sampling sites in the UK decreased with increasing KOA, indicating that the soil is an important source of lighter PAHs. This means that in agreement with previous works, the air concentration of the low molecular weight PAHs in the temperate areas is now being mostly controlled by the re-emissions of these chemicals from the soil. In order to study the influence of soil characteristics and temperature on gradients, the soil to ambient air fugacity ratios (fs/fa) were regressed against the different parameters describing the soil properties by equation: fs/fa= a + b (1/T) + c (log redox), thus indicating that the fugacity ratios increase at higher temperatures, and higher soil redox potential. The influence of the temperature is consistent with the seasonal variability and demonstrates that during warm periods soils increment their strength as a source. The influence of redox potential can be related to SOM quality or to soil microbiology, an important factor that could be related to in-situ production of PAHs from degradation of organic matter. The potential influence of soil emissions of PAHs as a factor controlling atmospheric concentrations of PAHs is discussed.

**EC02B-6**

**Atmospheric deposition fluxes of contaminants close to a municipal solid waste incinerator**

E Venturini[1], I Vassura[1], F Passarini[1], L Ferroni[2], L Morselli[1]
[1]University of Bologna, BOLOGNA, Italy
[2]University of Bologna, Rimini Branch, RIMINI, Italy

European committee for standardisation approved on October 2009 EN 15841, the Standard method for determination of arsenic, cadmium, lead and nickel in atmospheric deposition. It recommends the use of bulk collectors, as Italian National Institute of Health (ISS) had already indicated. In this study atmospheric depositions were collected with bulk samplers, with the same features indicated in the new standard method. The goal of this study is to assess the contribution of a Municipal Solid Waste incinerator to the area's total contamination with polychlorinated dibenzodioxins and polychlorinated dibenzofurans (PCDDs and PCDFs), polychlorinated biphenyl (PCBs), and heavy metals (HM). New generation plants, built after European Directive 2000/76/EC and the implementation of Best Available Techniques (according to IPPC Directive 96/61/EC), reduced the emissions of pollutants. However the locally contribution of POPs and HM in the flux depositions could be not negligible. The incineration plant studied is situated in a suburban area, not far from a tourist town (Riccione), an important Italian highway (A14), and the Adriatic coast. This plant is authorized to burn 127,600 t per year of urban, hospital, and cemetery solid waste. Samples were collected at five sites, three situated in the area most affected by plant emissions (according to the results of the Calpuff air dispersion model), one in an external site, considered as a reference, and one in an urban site. From 2006 to 2010, bulk atmospheric deposition samples were collected monthly for heavy metal analysis and at intervals of about 6 months for PCDD/Fs and PCBs analysis.

Results show that the studied area is subject to low contamination, as far as these compounds are concerned. Deposition flows show no significant differences among the monitored sites. However some temporal trends can be observed. In conclusion, the incineration plant is not the main source of pollutants in the studied area, which is apparently characterized by a homogeneous and widespread contamination situation, typical of an urban area. This is confirmed by the observation that deposition flows are not significantly lower than the other years, even though the plant was shut down for 6 months.

## EC03 - Biodegradation and bioremediation of organic pollutants

**EC03-1**

**Assessing bacterial diversity and its influence on biodegradation potential**

RJ Davenport[1], AK Goodhead[2], JR Snape[3], TJ Martin[1], JF Jon[4], T Madsen[5], AR Pedersen[5]

[3]Brixham Environmental Laboratory, AstraZeneca UK, BRIXHAM, United Kingdom
[4]Pfizer Inc., NEW YORK, United States of America
[5]DHI, HØRSHOLM, Denmark

Biodegradation - and its corollary, persistence - is an important but poorly understood fate process that is central to all mitigation strategies, both at pre-manufacture stage of chemicals, and when they are eventually present in the environment. It represents one of the greatest scientific uncertainties in assessments (e.g. life-cycle, fate and exposure models) that underpin EU directives affecting their control (e.g. REACH, IPPC, WFD). Biodegradation is often measured experimentally by observing the degradation of a chemical substance in the presence of a bacterial inoculum, and relies on the probabilistic inclusion of specific degraders in the test system. They usually rely on one or a few inoculum sources and chemical substances. Ready biodegradability tests (RBTs) have long been the central foundation for understanding the biodegradation of chemicals in regulatory frameworks, but a recent shift in emphasis towards identifying persistent chemicals has resulted in REACH guidance advocating the use of longer duration tests with environmentally-relevant inocula concentrations.

Little is kown about the natural variation in biodegradation potential of different environmental compartments or how bacterial diversity influences such variation. We have recently been investigating how inoculum source, concentration, bacterial community composition and diversity (and the factors thought to impact it) affect biodegradation outcome. To achieve this we have been conducting inocula sample surveys, applying the latest molecular methods to characterise their diversity and subjecting them to novel miniaturised high-throughput biodegradation tests. One of our aims is a better understanding of biodegradation for the development scientifically sound screening tests for persistence.

**EC03-2**

**The biodegradation of para-nitrophenol in river water: a functional gene approach**

A Kowalczyk[1], RA van Egmond[2], CJ Finnegan[2], OR Price[2], H Schafer[1], GD Bending[1]
[1]The University of Warwick, WELLESBOURNE, United Kingdom
[2]Safety & Environmental Assurance Centre, Unilever, SHARNBROOK, United Kingdom

OECD chemical biodegradation tests are conducted in the dark using unrealistically high concentrations of test chemicals. We investigated the effect of light on the biodegradation of *para-* nitrophenol (PNP) and the associated impacts on bacterial community composition. The biodegradation of PNP was followed over 100 days in water collected from the River Dene (Wellesbourne, UK). Total degradation of PNP at the concentration of 2mg/L occurred within 7 days in the dark, while degradation under light conditions was inhibited with only one replicate degrading (93%) after 56 days. Cultivable PNP degrading bacteria were not detected under light conditions. However, under dark conditions after 100% degradation of PNP, $10^5$ cells/mL of cultivable PNP degraders were detected. Terminal Restriction Fragment Length Polymorphism of the16S rRNA gene indicated that bacterial community structure was differentially affected by dark and light conditions and that an isolated PNP degrader, *Pseudomonas syringae*, proliferated in the dark bottles but was absent from the light bottles. In addition, a fragment of PNP degradative gene *pnpA* (~267bp) was amplified from *P. syringae* which confirmed that this strain was a key PNP degrader *in situ*.

**EC03-3**

**Impact of cell concentration methods on the performance of enhanced biodegradation tests within REACH**

TJ Martin[1], RJ Davenport[2], AK Goodhead[2], M Daniel[3], A Bartram[3], JR Snape[3]
[1]AstraZeneca UK Ltd / Newcastle University, BRIXHAM, DEVON, United Kingdom
[2]Newcastle University, NEWCASTLE, United Kingdom
[3]AstraZeneca UK Ltd, BRIXHAM, United Kingdom

Regulatory emphasis has shifted recently towards hazard identification and prioritising chemicals which are persistent, liable to bioaccumulate and are toxic, since chemicals with these properties have previously been shown to be most harmful to human health and the environment. Biodegradation is one of the most important fate processes determining persistence. Ready biodegradability tests (RBTs) have formed the core protocol for developing regulatory guidelines for persistency and environmental exposure assessments. They are highly prescribed, very stringent standardised tests that measure the biodegradability of chemicals. Due to the stringent nature of the tests and their high false negative rate, they offer little potential for prioritising on the basis of environmental persistence. This has been recognised in REACH guidance which advocates the introduction of a new tier of enhanced tests to enable efficient and effective identification of persistent chemicals. Reliable extrapolation from any small-scale systems to predict effects at local and regional levels are dependent upon test systems truly being representative of the real environment, including the nature of the microbial populations present. Enhanced tests allow increases in inoculum density to environmentally-equivalent concentrations, thereby incorporating increased and realistic microbial diversity. This presentation will describe the application of the latest molecular techniques and ecological models to quantify the distribution, abundance and diversity of bacteria in different environmental compartments and their influence on biodegradation outcome, with the eventual aim of developing robust screening tests for persistence.

**EC03-4**

**Degradation of PFCs by anaerobic bacteria**

JR Parsons[1], V Albergamo[1], F Maphosa,[2], H Smidt[2]
[1]University of Amsterdam, AMSTERDAM, The Netherlands
[2]Wageningen University, WAGENINGEN, The Netherlands

PFOS, PFOA and other PFCs are considered to be persistent compounds in the environment due to the highly stable C-F bond. Nevertheless, there are examples of microbially catalysed defluorination reactions, such as those observed for fluorinated acetates and benzoates. Reductive defluorination reactions under anaerobic conditions are exothermic. Such reactions could potentially serve as a terminal electron accepting process for anaerobic bacteria, as is the case for many reductive dechlorination reactions. A large number of anaerobic bacteria have been identified that use reductive dechlorination as an electron accepting process, often referred to as chlororespiration. Since the dehalogenases present in reductively dechlorinating bacteria may also be active towards other organohalogen compounds, we have tested a number of reductively dehalogenating bactera with PFCs. Several Desulfitobacterium strains, including Desulfitobacterium sp. PCE1, D. hafniense DCB-2, D. hafniense TCE1 and D. chlororespirans Co23 were incubated with PFOA and PFOS under anaerobic conditions. Culture samples were analysed by LC-MS/MS over a period of 14 months for PFOS, PFOA and their putative metabolites. First results from these experiments indicate that some of these strains are indeed able to dehalogenate PFCs.

**EC03-5**

**Monitoring the transport and degradation of triclosan in field soils receiving sewage sludge**

E Butler[1], MJ Whelan[1], R Sakrabani[1], R van Egmond[2]
[1]Cranfield University, BEDFORD, United Kingdom
[2]SEAC, Unilever, BEDFORD, United Kingdom

The anti-microbial substance triclosan has widespread use in home and personal care products. It is moderately hydrophobic and can, therefore, partition to sewage sludge following waste water treatment. A field experiment was conducted over a 12 month period between November 2009 and October 2010, in order to track the fate of triclosan in three different soils (a sand, a sandy loam and a clay soil) in Eastern England following the application of sewage sludge. Three replicate plots were established on each soil. Dried sewage sludge pellets with a native triclosan concentration of 15-38 mg kg-1 were manually incorporated into the top 10 cm of each plot at an application rate equivalent to 50 tonnes per hectare. Monthly soil samples were taken at three depths (0-10, 10-20 and 20-30 cm). Triclosan concentrations were measured using GC/MS following accelerated solvent extraction (ASE) and solid phase extraction (SPE). Concentrations in the top 10 cm were initially very high in all plots (850-900 _g kg-1) but decreased progressively. Relatively rapid methyl-triclosan formation was measured in the sand and the loam soils between March and June, suggesting that triclosan biodegradation accelerated over this period. Methyl-Triclosan is a known methylated metabolite which is more lipophilic and is believed to be more environmentally persistent than the parent compound. Degradation was less pronounced in the clay soil and there was triclosan translocation to the lower horizons (20-30 cm). This probably reflects an increased retention of triclosan in the soil solid phase due to a higher organic matter content in this soil. Most triclosan movement was observed in the sandy soil, reflecting better drainage and associated leaching of solutes and colloids. After 12 months, triclosan concentrations had decreased to 15-20% of initial concentrations in the top 10 cm of soil. However, triclosan and methyl triclosan concentrations in the lower soil horizons (10-30 cm) were detectable. The results of this study provide evidence for triclosan degradation and leaching in different field soils and highlight the role of soil properties in controlling environmental fate.

**EC03-6**

**The effect of non-UV light on the microbial degradation of crop protection products in an aerobic soil system**

LO Davies[1], GD Bending[2], H Schäfer[2], R Oliver[3], I Bramke[3], S Marshall[3], C Nichols[3], E France[3]
[1]Warwick University/Syngenta, WELLESBOURNE, United Kingdom
[2]Warwick University, WELLESBOURNE, United Kingdom
[3]Syngenta, BRACKNELL, United Kingdom

Crop protection products (CPPs) are subject to strict regulatory processes prior to approval for commercial use. Laboratory studies are routinely used to study the environmental fate of CPPs, however systems may not provide an accurate representation of field conditions, and therefore extrapolation of data to a field environment is questionable. It is therefore essential to add complexity to laboratory studies to create a more environmentally realistic system. The following study investigates aerobic degradation studies of CPPs in soil which are typically conducted under dark conditions. The effect of phototrophic organisms on the transformation of CPPs was investigated by the inclusion of non-UV light to standard laboratory systems. A preliminary experiment compared the time it takes for 50%/90% of a compound to degrade (DT50 and DT90) for the experimental fungicide "fungicide A"and the herbicide chlorotoluron. A second experiment compared the transformation of several CPPs at a single sampling point; namely, prometryn, cinosulfuron, imidacloprid, lufenuron, propiconazole, and fludioxonil.
The DT50 of fungicide A was approximately halved from 373d to 183d under dark and light conditions, respectively. The DT90 of chlorotoluron was similarly halved from 79d to 35d under dark and light conditions, respectively. Experiment 2 showed a significant reduction ($p \le 0.05$) in extractable parent compound under light for prometryn (4%), imidacloprid (8%), and fludioxonil (24%). Cinosulfuron behaved atypically to other compounds with a 14% increase in extractable parent compound under light ($p \le 0.05$). There was no significant difference in CPP transformation under light for propiconazole and lufenuron. Chlorophyll $\alpha$ was significantly higher under light treatments for all compounds tested ($p \le 0.05$) indicating the presence of phototrophic organisms in these systems. The enhanced rates of degradation observed for the majority of compounds may be due to direct degradation by phototrophic organisms or an increase in viable biomass/microbial activity from the addition of C produced by photosynthesis.
Light treatments displayed significantly higher bound residues for six of the compounds tested ($p \le 0.05$), which may be due to; (i) 14CO2 assimilation by phototrophs; (ii) Degradation by photosynthetic or non-photosynthetic organisms, or; (iii) Sorption of CPPs to soil particles.

## EC04 - Environmental fate and bioaccumulation of organic pollutants in aquatic systems

**EC04A-1**

**Atmospheric transport and bioconcentration in plankton of chlorinated persistent organic pollutants in the Greenland current and Arctic Ocean**

CJ Galbán-Malagón, MJ Ojeda, N Berrojalbiz, J Dachs
IDAEA-CSIC, BARCELONA, Spain

Occurrence of POPs in the North Atlantic and Arctic Ocean is one to most important issues in the actual Global Change Scenario and during the last Decades. The Transport and subsequent deposition of this Pollutants to the Arctic has been studied extensively in the literature from the North American and Eurasian plateau but there is a lack of Knowledge about the transport of pollutants trough the North Atlantic and Arctic (Gioia et al., 2008; Sobek et al., 2004 and 2006). Several studies reported smaller latitudinal gradients and decreasing concentrations, from Europe to the Sub Arctic Ocean and Ice Covered Regions. Published results in this area did not report particulate, aerosol and Phytoplankton concentrations this study is the first showing this concentrations at the same time in the studied area. No residence times are published for pollutants in this area, this work is the first showing residence times in a latitudinal gradient, that could be compared to models published before (Jurado and Dachs., 2008). Fugacity results are shown for the first time in North Atlantic and Arctic-SubArctic area. This is an important standpoint for future research in order to give a better perspective in the study of the transport and cycling of these pollutants in the area.

**EC04A-2**

**LC-MS/ MS analysis for the identification and quantification of endocrine disrupters in surface water and in water for human consumption: monitoring of italian water supplies**

S Bogialli[1], L Achene[1], L Lucentini[1], E Ferretti[1], F Nigro di Gregorio[1], F Palumbo[2], E Raffo[2], M Ottaviani[1]
[1]Italian National Institute of Health, ROME, Italy
[2]AMGA Foundation, GENOVA, Italy

The presence of endocrine-disrupting compounds (EDs) in influent and effluent water samples from six waterworks located in Italy was studied. EDs may exhibit physiological effects at very low concentrations.
An advanced analytical method was developed using solid-phase extraction (SPE) and liquid chromatography-tandem mass spectrometry (LC-MS/MS) for the simultaneous identification and quantification of selected Endocrine Disrupters (EDs) in raw and treated waters.
Analytes were pre-concentrated from 1-L water samples by SPE on HLB cartridges and analysed by reversed-phase LC-MS/MS. The mass spectrometer was operated in multiple reactions monitoring mode with ionspray interface in negative ionization mode using 17β-estradiol-d3 as internal standard. Moreover, the analytical protocol was modified in order to make it suitable to treated waters. A collaborative trial was conducted among the waterworks with the aim to evaluate the reliability of the analytical protocol for analyses of surface waters. The method was validated in term of sensitivity, selectivity, trueness, repeatability and inter-laboratory precision. Data on both the state of contamination of water for human consumption and on the efficiency of the treatment processes in removing EDs were obtained as a result.
The maximum concentration value in the influent water samples was 806 ng/l (nonylphenol), being all these values are comparable with the concentrations reported to be found in European surface waters.
Finally, the treatment processes used to make potable water destined to human use was evaluated in terms of ability in removing selected EDs: a complete or significant reduction of EDs contamination were always observed, with residual concentration level in the range of ng/L.

**EC04A-3**

**Modelling the coupling of biodegradation with air-water exchange and its influence on POP concentration in plankton**

N Berrojalbiz, J Dachs
IDAEA-CSIC, BARCELONA, Spain

Atmospheric deposition, and particularly diffusive air-water exchange, is the main entrance and driver of the concentrations of many persistent organic pollutants (POPs) in the surface waters

of open oceans and Lakes. Once in the water, partitioning processes influence the transport pathways, degradation processes, residence times and the final fate of the compounds. Indeed, it is known that biogeochemical cycles, especially those related to organic carbon, affect the POP transport and sinks in the water column. The biological pump has received a lot of attention during the last decade, but it is not clear the role of biodegradation on air water exchange and accumulation of POPs in planktonic food webs. Therefore, the main objective of this estudy is to clarify the interactions of atmospheric inputs of POPs and the biogeochemical processes occurring in the surface ocean mixed layer emphasizing the implications of the biological pump and degradation in such processes.
Air-water-plankton coupled model has been developed modifying the approach proposed by Dachs and coworkers (1) to calculate air-water, water-plankton and settling fluxes. Additional modeling exercise has been used to include the potential degradation process occurring in the water column. Field measurements have been used in the validation of the model. All samples were obtained on board of RV-Garcia del Cid research vessel during two Mediterranean sampling cruises on June 2006 and May 2007.
Air-water-planton model for more persistent POPs (PCBs and HCB) obtains not only good agreement for measured plankton concentrations, but also has been able to reproduce the seen dillution effect. On the contrary, more labile compounds such as low molecular weigh PAHs and HCHs require to integrate the biodegradation processes occurring in the water column to reproduce more accurately field measurements. The trends observed in the Mediterranean provide important clues on the processes driving POPs in other oceanic regions, where the gradients in biomass and other environmental variables can be larger than in the Mediterranean.

**EC04A-4**
**Vertical eddy diffusion as a key mechanism for removing perfluorooctanoic acid (PFOA) from the global oceans**
R Lohmann[1], E Jurado[2], HA Dijkstra[2], J Dachs[3]
[1]University of Rhode Island, NARRAGANSETT, United States of America
[2]Utrecht University, UTRECHT, The Netherlands
[3]IDAEA-CSIC, BARCELONA, Spain
The objective of this work is to estimate the importance of vertical (eddy) diffusion as a major removal process of POPs from the surface ocean. We focus on PFOA as a tracer as it represents a stable, highly water-soluble molecule and has recently been proposed as a novel chemical tracer of ocean circulation. As the ocean is generally vertically stratified, there are large concentration gradients with depth, so turbulent vertical eddy diffusion becomes a key process in removing compounds from the surface layer. Vertical eddy diffusivities are highly variable both in time and space, ranging from 10-2 m2 s-1 in the upper mixed ocean to 10-5 m2 s-1 in the open deep ocean. In this paper, we use such a three-layer vertical eddy diffusion turbulence model to study removal of PFOA from the upper ocean. Values of E are estimated using measured vertical profiles of PFOA, and compared to literature values. These E values are next extrapolated to obtain values for the global ocean and then used to obtain global vertical fluxes of PFOA. We attempt to (i) explain observed vertical PFOA profiles in the Japan Sea and Mid-Atlantic Bight solely based on transport through vertical eddy diffusion, (ii) derive the flux of PFOA at 100 m depth from measured global surface ocean concentrations of PFOA, (iii) estimate historical global ocean vertical diffusion fluxes of PFOA, and (iv) compare the importance of deep water formation and vertical eddy diffusion in removing PFOA from the surface water. The North Atlantic emerged as the main sink for PFOA, with accumulated removal fluxes over the last 40 years of 220 - 890 t, with the South Atlantic contributing another 90 - 360 t. The Pacific Ocean is estimated to have around 260-1,100 t PFOA below a depth of 100 m, while the Indian contributes only between 15 -60 t in total. To put the vertical diffusive flux values in the global oceans in perspective, we estimated the flux of PFOA entering the deep ocean via deep water formation. Total amounts moved by deep water formation are estimated to be 50 - 250 tons in the Norwegian Sea and 30 - 130 tons of PFOA in the Labrador Sea over the last 40 years. Thus, vertical eddy diffusion accounts for losses of PFOA to depth on the order of 620 - 2,400 t, while 80 - 360 tons have been lost from the surface oceans via deep water formation.

**EC04A-5**
**Latitudinal distribution of polyfluorinated organic compounds in the air and surface water from the Arctic to the Antarctic**
Z Xie[1], L Ahrens[2], A Möller[1], R Sturm[1], R Ebinghaus[1]
[1]Helmholtz-Zentrum Geesthacht, GEESTHACHT, Germany
[2]Environment Canada, ONTARIO, Canada
Per- and polyfluorinated organic compounds such as perfluorocarboxylic and sulfonic acids, perfluoro alkyl sulfonamide and N-substituted sulfonamides (PFASs), and fluorotelomer alcohols (FTOHs) are substances that have been extensively used and applied in industrial and consumer products in the past 50 years due to their surface-active properties and thermal as well as chemical stability Scientific concern about PFCs increased due to their global distribution and ubiquitous detection in the environment and biota. Recent studies conducted in the presence of PFCs in wildlife from the Arctic have demonstrated that these chemicals are widespread in these regions and accumulated in the food chain. More studies are required to resolve how PFCs transport from the sources to the coast and marine environment.
The objectives of this study are to characterize the distribution of PFCs in the atmosphere and sea water of the Atlantic, Arctic and the Antarctic. Data will be used to estimate the transport path of PFCs from high contaminated region to relatively low contaminated region, and evaluate the air-sea gas exchange intervening in the transport process of PFCs into the Open Ocean and Polar Regions.

Polycyclic aromatic hydrocarbons (PAHs) are a group of semi-volatile organic compounds (SOC) which are ubiquitous in the environment, bioaccumulate in planktonic food webs and may cause a wide range of toxic effects in biota and humans. The atmosphere is their major pathway of transport and deposition for PAHs, being partitioned between the air gas and aerosol phases. There is little information on the PAH occurrence and deposition in marine environments far from shore areas (open sea). PAH atmospheric concentrations, spatial distribution and deposition across the Mediterranean Sea and in the Marmara and Black Seas are presented in this work. Data were collected during two sampling cruises performed on June 2006 and May 2007 on board of the oceanographic vessel B/O García del Cid (CSIC). In both campaigns, Barcelona was the initial and final port, with Istanbul and Alexandria being the intermediate stops respectively. A total of 44 integrated air samples (particulate + gas phase) were collected mostly along the Mediterranean but also in the Marmara and Black Seas by using high volume samplers. PAH atmospheric levels over the Mediterranean Sea were driven by air gas phase concentrations. ∑16 PAHs gas phase concentrations ranged from 2 to 4 ng m-3 whereas particulate phase concentrations varied from 0.1 to 0.3 ng m-3. The transect encompassing the Marmara and Black Seas exhibited a slightly highest PAH concentrations of 6 ng m-3 and 0.5 ng m-3 for gas and particular phases, respectively. Phenanthrene dominated the average gas phase congener pattern in the Mediterranean Sea accounting for 50 ± 15% of the sum of PAHs, whereas PAH congeners were more evenly distributed in the particulate phase being Benzo(b)fluoranthene and Benzo(e)pyrene the more abundant (12 ± 2% of the sum of PAHs). Dry atmospheric deposition fluxes in the Mediterranean Sea open waters ranged from 20 to 50 ng m-2 d-1, whereas in the Marmara and Black seas a value of 95 ng m-2 d-1 was calculated. Back trajectories analysis, diffusive air-water exchange and day and night concentration variations were also investigated in the present study.

**Fate of hydrophobic persistent chemicals in the pelagic system of Lake Maggiore during an algal bloom**
L Nizzetto[1], R Gioia[2], J Li[3], KC Jones[2]
[1]Norwegian Institute for Water Research, OSLO, Norway
[2]Lancaster Environment Centre, LANCASTER, United Kingdom
[3]Chinese Academy of Sciences, GUANGZHOU, China
Modelling studies have supported the hypothesis that carbon-rich/biogenic particle dynamics control environmental fate of hydrophobic chemicals such as POPs in pelagic ecosystems. In particular algal blooms represent highly dynamic scenarios with enhanced organic carbon synthesis and grazing. Studying these un-steady systems can provide useful information on the dynamics of pollutants entrance into the pelagic food web, and the organic carbon control on the chemical inter-compartment exchange. Polychlorinated biphenyls (PCBs) (as a model for hydrophobic accumulative substances) were measured in the dissolved and different particulate matter fractions of the pelagic ecosystem of Lake Maggiore (Italy) during the spring algal bloom between March and May 2009. In order to assess: i) the effects of biomass development on the air-surface exchange of chemicals; ii) the effects of biomass growth on the concentration of chemicals in the dissolved phase; iii) the distribution of PCBs across the different particle fractions; and iv) the state and the evolution (with time) of the POC-water partitioning. The majority of PCBs were associated with the dissolved phase followed by the colloidal fraction and the 0.5-10 um fraction, while less than 1% of the PCBs was associated with fractions 10-95 um, 95-200um and >200um. PCB concentration in the dissolved phase decreased with increasing chlorination and with time during the algal bloom. The plot between Log KOW and the LogKOC/water (namely the partitioning between the OC in a given fraction and water) showed low values of the slope in the central part of the campaign, suggesting conditions far from the partitioning equilibrium or variability of parameters controlling the partitioning.

**EC04B-2**
**Spatial and temporal dynamics of POPs in the Morava river**
R Prokes, K Kubosova, J Klanova, B Vrana, K Hilscherova
Masaryk University, BRNO, Czech Republic
Spatial and temporal dynamics of polyaromatic hydrocarbons (PAHs) in river sediments were a subject of the large scale study in the river shed of Morava river in the Czech Republic, the industrial area with frequent occurrence of floods. Following the studies focused on behavior of PAHs during floods (transfer of these compounds from bottom sediments to alluvial soils) and in the periods following floods (building up new burdens in sediments), the long-term study reported here was designed. Samples of river sediments from five sampling sites have been sampled for one year with the sampling period of four weeks. In addition to surficial bottom sediments, the samples of suspended material collected in the sedimentary traps, silicon rubber based passive sampler providing information on truly dissolved concentrations of chemicals of interest, and bulk water samples were taken every four weeks. All samples were analyzed not only for PAHs but a number of other legacy and emerging groups of persistent organic pollutants (POPs), they were characterized for their abiotic parameters and correlations of the POP levels with such parameters as well as with the meteorological and hydrological conditions were studied. Distribution of PAHs among the phases of aquatic ecosystem was also assessed, including spatial and temporal variability of such distribution. Such sampling design covered various seasons, temperature conditions, and hydrological situations and allowed for detail assessment of PAH behavior in highly dynamic river system. The results were further correlated with the results of toxicological assessments.

**EC04B-3**
**Distribution and fate of musk compounds in a river: field study and model calculation**
HG Streck
Helmholtz Centre for Environmental Research - UFZ, LEIPZIG, Germany
Synthetic musk compounds are widely used as ingredients in personal care products. They have been recognized as important organic pollutants in aquatic ecosystems, and are in general introduced into the environment via waste water treatment plants (WWTPs). This contribution describes a comprehensive study on the distribution and fate of 13 different musk compounds and 3 further compounds (triclosan, diphenylsulfone, benzophenone). The study was conducted at the river Bilina (discharge < 5 $m^3$/s; Czech Republic) from headwaters to its mouth. Main goals of the study were to gather data on the distribution and fate of compounds originating from personal care products, to collect data on bioaccumulation of the targeted compounds especially in fish and to assess their impact on the riverine ecosystem.
Water samples (bulk and passive sampling), suspended particulate matter, sediments and fish were collected during several sampling campaigns at different seasons and analysed. Simple model calculations were used to calculate mass fluxes between the compartments and to get a better understanding of the targeted compounds' fate.
Freely dissolved water concentrations reached values of up to 152 ng/L for diphenylsulfone and 106 ng/L for the musk galaxolide. Most compounds showed elevated concentrations downstreams of the WWTPs. By and large, patterns of distribution of the compounds along the river

did not differ at different seasons, pointing at a constant composition of the waste water throughout the year. Remarkable differences in sediment concentrations were determined in dependence of sampling depth, indicating different sedimentation history and temporal changes in pollution of the river. The results clearly showed that explaining sediment-water distribution of compounds should take the spatial heterogenity (horizontal and vertical) of sediments into account. Field data confirmed that musk compounds bioaccumulate in fish. No bioaccumulation in fish was observed for the bactericide triclosan.
A comparison of measured concentration data with acute and chronic toxicity values for organisms from three trophic levels (algae, daphnia, fish) revealed that all compounds except triclosan and galaxolide were at least three orders of magnitude below EC50-values. The concentrations of triclosan, and to a lower extent that of galaxolide, raise concerns about possible adverse effects on the ecosystem, and further monitoring of this compound is advisable.

**EC04B-4**
**Chiral signatures of selected pharmaceuticals as markers of biological attenuation processes in rivers**
S Chiron[1], Z Li[2], H Fenet[2], E Gomez[2], C Casellas[2]
[1]Aix-Marseille University, MARSEILLE, France
[2]Montpellier University, MONTPELLIER, France
The capacity of rivers for biological attenuation processes of trace polar organic pollutants are probably significant but poorly understood because the many factors (i.e., dilution, sorption, phototransformation, biotransformation) that control naturally attenuation are interrelated and difficult to study in isolation. Although it is possible to estimate in-stream attenuation rates from monitoring data, accurate estimates require large data sets. To overcome these limitations, chirality has been exploited in this work since only biological processes might change the enantiomer composition of chemicals. The main aim of this work was to investigate the chiral signature of the antidepressant venlafaxine and the β-blocker metoprolol to get insights into biological attenuation processes in river environment. This work includes laboratory-scale experiments to assess the contribution of sorption, phototransformation and biotransformation processes to the overall attenuation of venlafaxine and metoprolol as well as field observations to validate laboratory results. During base flow conditions (summer), enantiomeric fractions (EF) of each compound remained constant while they fluctuated during rainfall events (fall). High flow conditions probably prompted the release of chemicals accumulated during the dry season in sediment, where enantioselective biotransformation probably took place. Investigating chiral signature of selected pharmaceuticals is a promising tool not only to discriminate between abiotic and biotic transformation processes in river but also to assess the spatial and temporal variability in biological attenuation processes.

**EC04B-5**
**Deconstructing complex aquatic systems: identification of active components and the metabolism of fludioxonil by phototrophs**
KA Thomas, LH Hand
Syngenta, BERKSHIRE, United Kingdom
Assessment of the environmental fate of crop protection products (CPPs) incorporates a range of standardized laboratory studies designed to assess hydrolysis, photolysis, sorption and microbial degradation. In such studies complex, natural processes are separated in order to provide simple, standardized laboratory based systems that conform to legislative guidelines. In the case of freshwater microbial degradation, CPP degradation is examined in darkness. Clearly, such studies differ greatly from real world conditions.
Previously, we demonstrated that the incubation of such systems under non-UV light, to enhance system complexity and real world relevance by including phototrophs,, increased the degradation rate of CPPs when compared to standard, dark incubated, systems (presented at SETAC, Seville 2009).
Although such work demonstrated the enhanced degradative capabilities of more complex, phototrophic inclusive systems, our understanding of the factors involved was limited. In phototrophic inclusive systems there are a range of metabolic processes and community effects that are absent in the standard laboratory systems: metabolism by macrophytes, algae and periphyton, and enhancement of bacterial and fungal communities by macrophyte root structures, algal biofilms and planktonic algae.
In order to assess the metabolic capabilities of the various community factions within these complex systems, and in an attempt to understand the role of phototrophs in enhanced degradation, we isolated sub-communities and individual species from complex, phototrophic inclusive test systems and investigated their capacity to degrade fludioxonil. We were thus able to demonstrate that algae and macrophytes are metabolically competent, in isolation from bacterial and fungal communities.
In this way we have demonstrated the intrinsic metabolic significance of Elodea canadensis as well as algae from three phyla (Chlorophyta, Cyanophyta and Bacillariophyta (diatoms)) in the fate of the fungicide fludioxonil. Thus, it seems that current laboratory test systems are failing to consider the role of active, competent organisms that are likely involved in the fate of crop protection products in surface water environments.

**EC04B-6**
**Determining air-water exchange, spatial and temporal trends of PAHs in an urban estuary using passive polyethylene samplers**
R Lohmann, M Dapsis, EJ Morgan, V Dekany, PJ Luey
University of Rhode Island, NARRAGANSETT, United States of America
Passive polyethylene (PE) samplers were deployed at six locations within Narragansett Bay (RI, USA) to determine sources and trends of freely dissolved and gas-phase polycyclic aromatic hydrocarbons (PAHs) from May to November 2006. Freely dissolved concentrations of PAHs were dominated by fluoranthene, pyrene and phenanthrene, at concentrations ranging from 10s - 1,000s pg/L. These were also the dominant PAHs in the gas-phase, at 100s - 1000s pg/m3. A general north-south gradient was observed, with higher freely dissolved concentrations near the urban center of Providence. By and large, all stations followed the same temporal trends, with highest concentrations (up to 7,300 pg/L for sum PAHs) during the 2nd of 11 deployment, coinciding with a major rainstorm. PAH concentrations declined gradually through deployments III, IV and V, and could be explained by an exponential decay due to flushing with cleaner ocean water during tides. The estimated residence time (tres) of the PAH pulse was 24 days, close to an earlier estimate of tres of 26 days based on salinity gradients. Air-water exchange gradients indicated net volatilization of most PAHs at Conimicut Point. Further south at Quonset Point, gradients had changed to mostly net deposition of the more volatile PAHs, but net volatilization for the less volatile PAHs. Based on characteristic PAH ratios, Mount Hope Bay and Poppasquash were affected by fuel spill-derived PAHs. Dissolved PAHs at the other sites seemed to originate mostly from the combustion of fossil fuels.

**EC04C-1**
**Stable isotopes and persistent organic pollutants patterns in an Antarctic food web**
CVZ Cipro[1], S Taniguchi[1], P Bustamante[2], RC Montone[1]
[1]IOUSP, SÃO PAULO, Brazil
[2]Université de La Rochelle, LA ROCHELLE, France
Samples of several Antarctic organisms in different trophic levels (invertebrates, fishes, birds and pinnipeds) were analysed for persistent organic pollutants (PCBs, DDTs, HCHs, HCB, PBDEs, mirex, aldrin, dieldrin, endrin and chlordane-related compounds) as well as for $\delta^{13}C$ and $\delta^{15}N$ stable isotopes. Collections occurred in King George Island (62º05'S, 058º23'W), Antarctica in the austral summers of 2004/05 and 2005/06, for the following species: krill (whole *Euphausia superba*), limpets (soft tissue from *Nacella concinna*), fishes (muscle from *Notothenia rossii* and *coriiceps*), birds (egg and liver from *Pygoscelis antarctica*, *papua* and *adeliae*, *Catharacta* sp and *Larus dominicanus*; only liver from *Daption capense* and *Macronectes giganteus* and only egg from *Sterna vittata*) and pinnipeds (fat from *Lobodon carcinophagus*, *Leptonichotes weddelli* and *Arctocephalus gazella*). In a general way the PCBs (from 6.82 up to 1821 ng $g^{-1}$ ww), HCB (from 0.060 up to 136 ng $g^{-1}$ ww) and DDTs (from 0.410 up to 524 ng $g^{-1}$ ww) were the prevailing compounds within the species averages. PBDEs were one to two orders of magnitude lower than the organochlorine groups. Limpets presented results about three times quantitatively higher than krill, which could be mainly due to larger life spans. Fishes showed similar results in comparison to literature, which are reflected in superior trophic positions. Bird samples, influenced by several ecological factors, showed quantitatively higher concentrations and qualitatively heavier PCBs profile as the northernmost the species reaches and the more opportunistic/scavenger feeding habit it has. The stratification in pinnipeds results can be interpreted in a similar way. Carbon stable isotopes allowed the identification of two clearly distinct origins for organic matter: marine phytoplankton more depleted in $^{13}C$, as seen in krill ($\delta^{13}C$ of -25.66"ð) and the more $^{13}C$ enriched microphytobenthos, as seen in limpets ($\delta^{13}C$ of -16.10"ð). Some effects account for intermediate values: diversified diet, $\delta^{13}C$ latitudinal variation for migrating species and trophic level (an evidently lower enrichment than nitrogen, but yet existent). Nitrogen isotopes ($\delta^{15}N$ from 4.51 up to 14.53"ð) showed patterns in accordance to literature and significant Pearson correlation preliminary results between $\delta^{15}N$ and several pollutants concentrations, which reinforces the biomagnification processes of such compounds.

**EC04C-2**
**Environmental monitoring of HBCD in Europe**
H Ruedel[1], J Mueller[1], M Ricking[2], M Quack[3], R Klein[3]
[1]Fraunhofer IME, SCHMALLENBERG, Germany
[2]Free University Berlin, BERLIN, Germany
[3]Biogeography - University of Trier, TRIER, Germany
Hexabromocyclododecane (HBCD) is a brominated flame retardant applied mainly in polystyrene foams as well as in flame retarded back-coats, for instance for upholstery textiles. During recent years, emission control programs have been implemented by the HBCD producers and users in order to reduce the environmental footprint. To assess the impact and relevance of these reduction measures, an environmental monitoring project was initiated in 2007. The project is designed to assess temporal trends over a period of up to ten years at different sites across Europe. The study focuses on compartments which are expected to be sinks for HBCD based on its physico-chemical properties and the life cycles of products containing HBCD. Samplings cover fish (every year) and suspended particulate matter (SPM; every second year). Selected sites are at the rivers Tees/UK, Western Scheldt/Netherlands, and Rhone/France as well as at Lake Belau/Germany. The later represents a site with little anthropogenic influence. At all sites bream, a bio-indicator for accumulation also used for the German Environmental Specimen Bank, were caught. In brackish water (Scheldt, NL), both sole and bream were collected. After sampling and dissecting the fish, muscle tissue was immediately frozen over liquid nitrogen. Annual samples of usually 15 fish per site were grinded and homogenized by cryomilling (pooled annual sample for each site). To assess variability, muscle tissue from individual fish were analysed for selected sites. SPM was sampled with passive sedimentation traps in the vicinity of sites where fish were sampled. SPM was collected from the traps every three months, freeze-dried and combined to annual samples for each site. HBCD analyses of annual pooled fish and SPM samples were performed applying a validated LC/MS-MS method that allows quantification of the major HBCD diastereomers (alpha-, beta- and gamma-HBCD). Results from the first three years of fish monitoring suggest that at three sites with diffuse exposure characteristics the concentrations of HBCD are decreasing. For example, the HBCD concentration of bream from the Rhone declined by about 60 % (from 1420 µg/kg lipid weight in 2007 to 531 µg/kg in 2009). Decreasing environmental HBCD concentrations seem to be consistent with the implemented emission control measures. However, at one site impacted by a former point source (i.e. Tees) no decreasing concentrations in fish could be observed over the indicated observed period.

**EC04C-3**
**Influence of gender and age on PCBs accumulation in Chelon labrosus**
JL Baptista[1], P Pato[2], S Tavares[1], E Pereira[2], AC Duarte[2], M Pardal[1]
[1]CFE - Center for Functional Ecology, COIMBRA, Portugal
[2]Department of Chemistry & Center for Environmental and Marine Studies (CESAM), AVEIRO, Portugal
*Chelon labrosus* is an important commercial species and has been studied worldwide. However this species has never been studied for polychlorinated biphenyls (PCBs). Due to that, the concentration of 13 PCBs were measured in muscles and livers, of males and females of C. labrosus, of different ages, allowing the estimation of PCBs bioaccumulation along the life span, in the Mondego estuary. The Mondego estuary presented a relatively low environmental contamination of PCBs, with levels of total PCBs (tPCBs) in the sediments, ranging from 0.28 to 2.0 ng $g^{-1}$ (DW). tPCB concentration in male muscle samples concentrations ranged from 7 to 14 ng $g^{-1}$ (DW) and in females from 4 to 8 ng $g^{-1}$ (DW). In male liver samples tPCB concentration ranged from 28 to 46 ng $g^{-1}$ (DW), while females concentration ranged from 25 to 38 ng $g^{-1}$ (DW). In males, liver and muscle PCBs concentration increase with age, with significant differences (p=0.005; p=0.029; p<0.05, respectively). In female samples, no significant differences were found along the life span (for both tissues), although liver concentration had a tendency to increase with age. Concerning the muscle samples, gender is the major factor contributing for bioaccumulation, while in liver samples is age. The most abundant congeners in all samples were CBs 138, 149 and 153.

**EC04C-4**

**Persistent chlorinated organic pollutants and the decline of Atlantic eels**

JD Byer[1], M Alaee[2], RS Brown[3], M Lebeuf[4], S Backus[2], M Keir[2], G Pacepavicius[2], S Trottier[4], PV Hodson[3]
[1]Queen's University / Environment Canada, BURLINGTON, Canada
[2]Environment Canada, BURLINGTON, Canada
[3]Queen's University, KINGSTON, Canada
[4]Fisheries and Oceans Canada, MONT-JOLI, Canada

There are concerns that chemical contaminants may have been a major contributing factor leading to the precipitous decline of Atlantic eels since the 1980s. In particular, polychlorinated dibenzo-*p*-dioxins (PCDDs) and dibenzofurans (PCDFs), polychlorinated biphenyls (PCBs), polychlorinated naphthalenes (PCNs), and dechlorane plus (DP) were investigated due to their persistence, bioaccumulation and toxic potential. American eel (*Anguilla rostrata*) were captured at reference and contaminated sites in rivers of eastern Canada tributary to the Gulf of St. Lawrence, including the St. Lawrence R., and from the Hudson R., New York, USA. European eel (*Anguilla anguilla*) from Belgium were also collected for comparative purposes. Extracts of whole fish homogenates were analysed by gas chromatography-high resolution mass spectrometry (GC-HRMS) to determine the concentration of PCDD/Fs, non-ortho PCBs, PCNs, and DP. The remaining PCBs were measured with GC-quadropole ion-trap MS/MS. The GC-HRMS and GC-MS/MS instruments employed electron ionization and were operated in selected-ion-monitoring mode and selected-reaction-monitoring mode, respectively. Concentrations of dioxin-like compounds were used to calculate 2,3,7,8-tetrachlorodibenzo-p-dioxin toxic equivalents (TEQs) using fish-specific toxic equivalency factors. Reference American eels had values ranging from 0.36-1.70 pg TEQ/g ww (geomean = 0.75 pg TEQ/g ww) and others ranged from 0.48-8.95 pg TEQ/g ww (geomean = 2.10 pg TEQ/g ww). About 10% of American eels had measured TEQs > 4 pg TEQ/g ww, which has been suggested as the threshold for impairment of embryonic development. The TEQs for the majority of samples, however, indicate that the current risk of toxicity related to dioxin-like compounds is low.

**EC04C-5**

**Study of bioaccumulation and metabolization of fluoxetine in benthic invertebrates by Micro-QuEChERS-NanoLC-Nano-ESI-MS/MS**

C Cren-Olivé[1], A Bulete[1], R Baudot[1], L Wiest[1], m Gust[2], j Garric[2]
[1]CNRS_SCA_USR 59, SOLAIZE, France
[2]CEMAGERF, LYON, France

Fluoxetine is a widely used antidepressant, frequently found in aquatic ecosystems, which presented dissimilar effects on the reproduction of two gastropod species, P. antipodarum and V. piscinalis. Recently it has also been measured in fish downstream of effluent discharges indicating a high bioaccumulation capacity in vertebrate aquatic wildlife. However no data is available on fate and metabolism of pharmaceuticals in invertebrates. To better understand the interspecific sensitivity the bioaccumulation of fluoxetine and its in vivo metabolization into norfluoxetine have to be explored in P. antipodarum and V. piscinalis.
This kind of study requires the development of analytical tools for extraction and analysis of traces of fluoxetine and norfluoxetine in biotic environmental matrices like water's benthic invertebrates. These gastropods weigh just a few milligrams. With such a small sample size, extraction step and analysis are more difficult. So, advanced technologies are required to seek drugs traces in complex matrices like gastropods.
In this aim, we have established an analytical strategy as which consists in one single extraction for fluoxetine and norfluoxetine based on QuEChERS method, followed by a nano-LC-MSMS analysis. Indeed, nano-chromatography coupled with mass spectrometry (nano-LC-nano-ESI MS/MS) increases sensitivity, reduces the required initial sample amount and is a good tool to answer this ecotoxicological issue.
Both gastropods highly bioaccumulated fluoxetine. However, P. antipodarum bioconcentrated more fluoxetine than V. piscinalis, which can only be partly explained by their lipid content. However, N-demethylation into norfluoxetine was similar in both snails, and far less important than in fish. It implied the occurrence of this metabolic pathway in mollusks. The higher sensitivity of P. antipodarum to fluoxetine than V. piscinalis was at least enlightened by its higher bioaccumulation capacity, but not by higher metabolization into an active metabolite.

**Analytical approaches for the investigation of emerging contaminants in sources and treatment systems for drinking water production**

MWM Tielemans[1], R ten Broek[1], K Lekkerkerker-Teunissen[2], JP van der Hoek[3], CJ Houtman[1]
[1]The Water Laboratory, HAARLEM, The Netherlands
[2]Dunea Dune and Water, THE HAGUE, The Netherlands
[3]Waternet, AMSTERDAM, The Netherlands

For their need of drinking water, millions of Europeans depend on surface waters, such as the rivers Danube, Meuse, Po and Rhine. In these waters, rapid improvements in chemical and bioanalytical techniques have led to the discovery of all kinds of so-called emerging contaminants at very low concentrations, including pharmaceuticals, illicit drugs, sweeteners, endocrine disrupting compounds and perfluorinated compounds. Some studies also reported the presence of traces of emerging contaminants in drinking water samples. Dutch drinking water companies therefore intensively investigate their water sources for the presence of emerging contaminants and their fate during treatment processes. A combination of analytical approaches is applied for this purpose, including chemical screening techniques, hyphenated target analyses, biological early warning systems, bioassays and effect-directed analysis (EDA) approaches. This presentation gives an overview of chemical and bioanalytical approaches applied to investigate Dutch drinking water sources and treatment systems. Examples are discussed of the use of sensitive and specific techniques such as CALUX reporter gene bioassays for the analysis of hormone-like activities and the development and application of a UPLC-MS/MS method for the determination of (sub) ng/L concentrations of new pharmaceuticals. As an example of pharmaceutical analysis employing direct injection a study will be presented investigating the removal efficiencies of several emerging contaminants in a pilot-scale advanced oxidation treatment process. Presented studies show that quality assessment of drinking water sources requires the use of the most suitable techniques: biological, chemical or combinations thereof. Due to ongoing analytical improvement, our knowledge on contaminants in drinking waters sources steadily increases and also our responsibility to act accordingly.

**EC05A-2**

**Pharmaceuticals and transformation products in surface water and drinking water**

L ter Laak, M de Jongh, PJF Kooij, AP van Wezel
KWR Watercycle Research Institute, NIEUWEGEIN, The Netherlands

Numerous studies describe the presence of pharmaceuticals in the water cycle, while their transformation products are usually not included. The current study is based on a monitoring campaign of ~30 common pharmaceuticals and transformation products in 14 surface waters, 10 pretreated surface water, 7 river bank filtrates and the 17 corresponding produced drinking waters. Various pharmaceuticals and transformation products were observed at concentrations of <10 to >100 ng/L in the water cycle. Concentrations were generally highest in surface water, intermediate in raw water and river bank filtrate and lowest or not even detected in produced drinking water. However, the concentrations of phenazone and its environmental transformation product AMPH exceeded surface water concentrations by almost one order of magnitude. Their high levels in river bank filtrate are likely a result of historical contamination thatare still present in river bank filtrate. Additionally, the concentration ratios of transformation products and parent pharmaceuticals were studied. Since some of these products have similar (pharmacological) activities as their parents, and they were observed at similar concentrations as their parents (i.e. phenazone, tramadol, venlafaxine, carbamazepine), monitoring transformation products is relevant. However, it was observed that 'product/parent' ratios varied less than a factor 5 over all samples (when quantifiable). This suggests that concentrations of transformation products might be estimated from concentrations of parents instead of beeing monitored. This should, however, be studied in more detail.

**EC05A-3**

**Pharmaceuticals and personal care products in urban receiving waters**

A Musolff[1], G Strauch[1], S Leschik[1], M Schirmer[2]
[1]UFZ - Helmholtz-Centre for Environmental Research, LEIPZIG, Germany
[2]Eawag - Swiss Federal Institute of Aquatic Science and Technology, DUEBENDORF, Switzerland

Pharmaceuticals and personal care products (PPCPs) and other organic micropollutant from wastewater sources pose a potential threat to aquatic ecosystems and the human health. Urban areas are prone to PPCP contaminations since here large amounts of wastewater are produced transported and treated. However, the spatial and temporal complexity of urban water and wastewater flow makes the assessment of PPCPs a challenging task. In this paper we quantify the contribution of different PPCP pathways (wastewater treatment plant effluents, combined sewer overflows and groundwater discharge) out of a mid-European urban drainage catchment and assess the temporal variability of this contamination. The study area is a catchment of wastewater (sewershed) which is in a corresponding position to the groundwater catchment and therefore allow for a joint analysis of water and matter fluxes. We conducted a monitoring over the course of 13 months including samples from untreated and treated wastewater, surface water and groundwater. The resulting samples were screened for six PPCPs and micropollutants: Bisphenol A, technical 4-nonylphenol, caffeine, galaxolide, tonalide and carbamazepine. The annual water flow to and from the sewershed was quantified using the data of the wastewater flow and results from a numerical groundwater flow model. The combination of annual water flow with the median contaminant concentration yielded the mass flow out of the sewershed by treated wastewater, combined sewer overflow and by groundwater discharge. The results demonstrate that the release of micropollutants from the sewershed to the receiving waters is not a result of the effluents of the municipal wastewater treatment plant alone. For caffeine, bisphenol A and nonylphenol, the input of untreated wastewater by combined sewer overflow to the surface water can make 8% to 89% of the total mass release. A significant portion of bisphenol A and nonylphenol is released by groundwater discharge out of the sewershed boundaries. Surface water concentrations and mass fluxes of caffeine, galaxolide and tonalide correlate negatively with the water temperature. Therefore, these substances are characterized by a pronounced seasonal occurrence with rapid removal in times of higher water temperature despite the higher input by combined sewer overflow events in this period. The results of this study underline the complex interplay of release and fate of PPCPs in urban areas.

**EC05A-4**

**Attenuation and dynamics of pharmaceuticals in a small German stream**

UK Kunkel, M Radke
University of Bayreuth, BAYREUTH, Germany

Pharmaceutical residues are commonly detected organic micropollutants in the aquatic environment. Their fate in rivers and the importance of individual attenuation processes (photolysis, biotransformation, and sorption) is still incompletely understood. Previous studies indicated that in rather deep and turbid rivers these potential processes not always result in a significant attenuation of pharmaceuticals. Therefore, we performed experiments at a stream with less turbid water and an expected increased exchange of river water and sediments to check dynamics and attenuation in such streams.
Experiments were carried out at the stream Gründlach, near Nuremberg, Germany. Composite samples were taken at both ends of a river stretch of approximately 12 km length located downstream of a sewage treatment plant. Moreover, pore water samples were taken and in-situ photolysis experiments at several sites within the river stretch were performed. The concentration of 15 pharmaceuticals was analyzed with HPLC-MS/MS after solid phase extraction.
Pharmaceutical concentrations varied at the first sampling site due to variable proportions of sewage water in the river. Concentrations and loads at the downstream sampling site were lower for most pharmaceuticals. In comparison to carbamazepine which was persistent, metoprolol was attenuated within the river stretch. This attenuation can be attributed to sorption and/or biotransformation since it was not susceptible to photolysis. For diclofenac, photolysis in unshadowed parts or the river stretch could also be relevant as we determined an in-situ photolysis half-live of a few hours.

Preliminary results of this study suggest that attenuation of certain pharmaceuticals in small streams can be relevant. Even within short river stretches pharmaceuticals can be eliminated due to the more intense exchange of river water with the sediment compartment and due to a higher efficiency of photolysis compared to large rivers.

**EC05A-5**

**Tracing micropollutants during riverbank filtration under restored and non-restored conditions at the River Thur**

J Hollender, S Huntscha, D Rodriguez Velosa
Eawag, Swiss Federal Institute of Aquatic Science and Technology, DÜBENDORF, Switzerland

Riverbank Filtration (RBF) is a widespread, low-cost method to achieve high quality drinking water. Since little is known about the fate of organic micropollutants during RBF and the influence of river restoration on the processes in the hyporheic zone and the aquifer, we investigated the fate of micropollutants from the river through different groundwater transects. The field site was located in the lower part of the Swiss river Thur catchment, which was partially subject to river restoration. Two piezometer transects were installed: one is located in a channelized part where drinking water is produced by RBF and the other in a restored part of the river. First a screening was carried out for over 200 polar organic micropollutants using LC-HRMS, later 78 compounds were analyzed with an online-SPE-LC-MS/MS-method. Highly spatiotemporally resolved sampling of river water and groundwater was conducted between 2008 and 2010. During the screening we found 98 compounds in concentrations between 0.1 and 400 ng/L. The concentration patterns of the compounds over the two transects indicate that the behavior of different compounds in the transects is highly diverse at one point in time. During low flow conditions the pharmaceutical transformation products N-Acetyl-4-aminoantipyrine and Atenolol acid showed fast decreasing concentrations indicating biological degradation whereas Carbamazepine and Sulfamethoxazole persisted. Benzotriazole concentrations remained high even after a travel time of over 10 days and reached the drinking water well at a concentration of 200 ng/L. During a high discharge event the pesticide MCPA was found in the river at elevated concentrations up to 650 ng/L. Concentrations in the restored transect were one order of magnitude lower in the first two wells without any notable retardation. In further wells and in the transect in the channelized part, no MCPA was found. These observations implicate a strong degradation of MCPA in the first meters of the aquifer. The difference in the two transects is consistent with known travel times, which are shorter for the restored transect indicating that the travel time is an important influence parameter on biological degradation. Micropollutants from urban sources, such as the pharmaceutical carbamazepine, exhibited decreasing concentrations in the river during high discharge events. This caused decreasing concentrations in the groundwater transects with some retardation in the channelized transect.

**EC05A-6**

**Mechanisms controlling the transport of carbamazepine and other trace organic compounds in a sand aquifer receiving wastewater discharge**

CJ Ptacek, MJ Sabourin, LG Groza, K Mclagan, WD Robertson, DW Blowes
University of Waterloo, WATERLOO, Canada

In North America, approximately 35% of wastewater currently is discharged to the subsurface using on-site wastewater disposal systems. As water demand increases, the volume of wastewater discharged to the subsurface also is expected to increase. While abundant information is available on the fate of wastewater macropollutants in the subsurface, there is limited information available on the fate of trace contaminants, including pharmaceutical and personal care products. Field investigations were conducted at a well characterized septic-system located in southern Ontario. At this site, wastewater is discharged to an anaerobic septic tank followed by infiltration through the unsaturated zone to the shallow water table. The disposal is seasonal, from May to October of each year. A detailed groundwater sampling network previously installed at the site was sampled both temporally and spatially for analysis of major water chemistry parameters and a suite of pharmaceutical compounds. In the groundwater zone, elevated concentrations of carbamazepine (up to 4000 ng $L^{-1}$), sulfamethoxazole (2000 ng $L^{-1}$) and ibuprofen (1,800 ng $L^{-1}$) were observed over 30 m from the wastewater disposal area. Concentrations of other pharmaceuticals, including gemfibrozil, naproxen and caffeine, were much lower and more variable. Laboratory column studies conducted to evaluate transport parameters of the pharmaceutical compounds under controlled flow conditions showed little correlation to the transport observed at the field site. Predictions based on the physicochemical properties of the compounds were in close agreement to the transport observed in the laboratory experiments. Predictions of field behaviour were less successful. Additional studies are required to further delineate the transport behaviour of pharmaceuticals in groundwater at wastewater disposal sites.

**EC05B-1**

**Micropollutant plume in Lake Geneva**

F Bonvin, R Rutler, T Kohn
Ecole Polytechnique Federale de Lausanne, LAUSANNE, Switzerland

To date, most research on environmental occurrence and fate of pharmaceuticals has focused on the presence of these compounds in rivers and streams, often at sites close to discharges of wastewater treatment plant (WWTP) effluent. However, only scarce data exists concerning the environmental fate of pharmaceuticals directly discharged from WWTPs into lakes. We assessed the spatial and temporal distribution of 39 priority pharmaceuticals and pesticides in Lake Geneva's Vidy Bay, which serves as the receptacle for the effluent of the WWTP of the city of Lausanne. Depth profiles of these substances were established between April 2010 and December 2010 in key locations in the Vidy Bay. These included the outlet of the WWTP, and two reference sampling sites located ca. 1.5 km upstream and downstream of the discharge point. Concentrations were measured using an analytical screening method based on ultra performance liquid chromatography coupled to a tandem mass spectrometer (UPLC-MS/MS).

A plume with significantly elevated pharmaceutical concentrations was detected in the water column above the point of wastewater discharge into the bay. The depth of the contamination hotspot varied with season, following the thermocline which decreased from a depth of 10m in April to 25m in October. The cold season led to straight temperature profiles, and allowed mixing of the water column. Explicitly, this caused the disappearance of the concentration peak above the WWTP discharge point and thus homogeneous vertical concentration profiles. Conductivity profiles were well-correlated to pharmaceutical concentrations, indicating that in the particular situation of wastewater discharge in Lake Geneva, it is possible to track the plume and estimate the micropollutant concentrations therein using conductivity measurements. To our knowledge this is the first reported micropollutant plume.

**EC05B-2**

**PPCPs in recycling of dairy wastewater in a reconstructed mixed forest - forage formation**

P Fine[1], O Bar-Shalom[2], D Markel[3], U Mingelgrin[1], A Nasser[1], Z Gerstl[1]
[1]Volcani Center, ARO, BET DAGAN, Israel
[2]Keshet, GOLAN HEIGHTS, Israel
[3]Israel Water Authority, TEL AVIV, Israel

The Golan Heights is a significant segment of the watershed of the Sea of Galilee, which comprises ca. 30% of the Israel's water supply. The alternatives for safe disposal of dairy farm sewage water are limited and sewage water might overflow into local streams, resulting in the uncontrolled dispersal of sewage water.

We have examined recycling of dairy effluents via irrigation of a mixed pasture - planted tree ecosystem. The effluent is stored in lagoons and used following minimal treatment.

We hypothesize that under deficit irrigation the migration of pollutants may be greatly retarded. We examined the partitioning of these contaminants between the: soil, soil solution, run-off, woody plant parts and grasses. This was carried out in two similar size drainage basins - one irrigated with wastewater effluent from a reservoir that received both dairy and human wastewater, and another non-irrigated basin. The latter basin was still under forage by ca. 1000 cows. Altogether 67 water samples were analyzed by LCMS.

The data show that PPCPs of both domestic and veterinary origin can be found in the soil extracts of the fields regardless of the irrigation regime. One compound (carbamazepine) was present in most of the water samples collected during 2009/2010 winter from the DWWE irrigated basin and also in 6 samples collected from the non-irrigated basin (that was under forage cows). The occurrence is a bit surprising owing to the almost strict domestic use of this chemical (and furthermore, one inhabitant only was prescribed to take the medication). Caffeine was the second most abundant compound under DWWE irrigation, yet it was first (7 out of 24 samples) in the irrigation-free basin, which is again quite unexpected. These two products are rather resistant in the environment and ubiquitous. Most all other PPCPs tested occurred in a small number of samples (1-8). The veterinary antibiotics were either missing altogether or occurred in 1-4 water samples from the irrigated site. At any event, the concentrations of those products that were detected were in the low range of 0.5-35 µg/L.

The research showed that recycling dairy wastewater through irrigation of a pasture - forest system under deficit irrigation poses little threat to PPCPs emission into water resources. Yet, this conclusion has to be reevaluated at this and other sites. In addition, it will be interesting to reveal the origin of PPCPs in the not-irrigated basin.

**EC05B-3**

**Dynamics of sulfadiazine in manure-amended soil under field conditions**

A Focks[1], I Rosendahl[2], T Müller[1], J Klasmeier[1], M Matthies[1], J Siemens[2], W Amelung[2]
[1]Institute of Environmental Systems Research, OSNABRUECK, Germany
[2]Institute of Crop Science and Resource Conservation, BONN, Germany

In the last years, environmental fate and effects of the sulfonamide antibiotic sulfadiazine (SDZ) have been investigated in a series of studies. Förster and co-workers quantified the concentration dynamics of SDZ and metabolites in soil by using a sequential extraction procedure (Förster *et al*, 2009, ES&T); and the respective fractions could well be described by a conceptual kinetic model (Zarfl *et al*, 2009, Chemosphere). The next step towards an advanced understanding of the environmental behaviour of SDZ was to investigate the fate dynamics of SDZ under field conditions. Respective experiments were performed and the conceptual model developed for batch experiments was tested for its ability to simulate the observed fate dynamics of SDZ under field conditions. The experimental field plots were cultivated with maize and grass. During the vegetation period, the plots were fertilized three times (day 0, 49, and 133) with manure originating from SDZ-treated pigs. Soil samples were taken from the top soil layer during the vegetation period; occasional sampling was continued until the following spring. The soil samples were sequentially extracted and measured following published methods. For modelling, $CaCl_2$ extractable and high-temperature extractable parts of SDZ were assigned to an 'easily extractable fraction' (EAS) and to a 'residual fraction' (RES), respectively. Reference values of kinetic rate constants from laboratory batch experiments at controlled temperature and moisture conditions were used for simulations. Sink rate constants ($k_1$) were corrected for actual temperatures by an Arrhenius-like function. Substance availability in EAS was scaled by the fraction of dissolved SDZ in EAS, depending on actual daily soil water contents. Experimental values of EAS and RES fractions showed elevated concentrations directly after application of manure to soil and decreasing concentrations in the following. In model simulations, concentration dynamics of the EAS fraction were fitted quite well by using temperature and availability corrected rate constants. However, the concentrations in the RES fraction were clearly overestimated. The simulation fit to the RES fraction could be improved by increasing the rate constants $k_1$ and $k_3$ by factors of 1.5 and 4.0, respectively. Identical rate constants could be used to describe two different trials where maize or grass was cultivated.

**EC05B-4**

**Generating screening-level scenarios of personal care products in China using GIS**

CM Holmes[1], V Vamshi[1], D Mao[1], J Mortimer[2], O Price[2]
[1]Waterborne Environmental, Inc., LEESBURG, VA, United States of America
[2]Unilever - Safety and Environmental Assurance Centre, SHAMBROOK, United Kingdom

The development and application of models to predict in-river concentrations of down-the-drain chemicals (i.e. those used in household and personal care products and pharmaceuticals) are important components of the environmental risk assessment process. While such models (e.g. EUSES and GREAT-ER) exist in Europe, there are currently no available models to estimate exposure of personal care products in China. To this end, work was performed to create a GIS-based system that develops scenarios used to predict the fate of "down the drain"chemicals into freshwater ecosystems. Currently, many of the available inputs for the generation of environmental concentrations to be used in the exposure assessment are at a very coarse spatial scale, in some cases only a single value for the entire country is available. In this study, Predicted Environmental Concentrations in surface water (PECsw) were generated at the county-level (ca. 3,000 counties in China) based on both user supplied product information, as well as other geographically-linked socio-economic and environmental information from official census and other data sources. Product information such as category (e.g., hair, skin, etc.), composition (e.g., ingredient fraction) and "take off "values (GDP threshold under which the product would not be purchased) were used to distribute total tonnes of individual ingredients used in China. These data were combined with county-level economic information, population density (including urban and rural separation), dilution factors, and disposal mechanism (e.g., STP, septic, direct discharge to river, etc.) to estimate ingredient-level PECs in surface water.

Results show that local PECsw varies considerably across the country and that economic information ("take off "values and population GDP) can have a significant influence on the resulting ingredient distributions. The method presented incorporates the inherent spatial variability of the model inputs so that patterns can be identified and used in the risk assessment. In other words, the ability to identify areas where existing combinations of model inputs may yield greater exposure estimates, i.e., the identification of realistic "worst case"scenarios. In addition, an understanding of where these "worst case"scenarios fit within the overall country-wide distribution (i.e., 90th percentile) is achieved.

**EC05B-5**

**Predicting the fate and behaviour of cyclic volatile methyl siloxanes in two contrasting lakes**

MJ Whelan
Cranfield University, BEDFORD, United Kingdom

The behaviour of three cyclic volatile methyl siloxanes (D4, D5 and D6) in lakes was explored using a fugacity-based steady-state non-equilibrium multimedia fate and transport model (a modified version of QWASI) in order to ascertain their likely environmental persistence and the relative importance of different loss processes (volatilisation, hydrolysis, burial in sediment and advection in outflow). Predictions were made for two contrasting North American lakes: Lake Ontario and Lake Pepin. Partition coefficients and the hydrolysis rate constant were adjusted for the mean annual temperatures of each lake. Half lives in sediment were calculated from partitioning theory, assuming that hydrolysis occurs only in the dissolved phase of the interstitial water. Estimates of substance-specific emissions were obtained by combining current per capita approximations of usage and fraction lost to domestic waste water, the population of the lake watershed and typical cVMS removal efficiency during waste water treatment. Predicted concentrations were generally lower and chemical residence times longer in Lake Ontario than in Lake Pepin, owing to greater depth, a much longer water residence time and a higher degree of dilution. Overall persistence in Lake Pepin was significantly influenced by the high rate of sediment burial assumed in the model, as well as by a relatively high rate of water discharge. Despite the many similarities of the compounds considered, the dominant loss mechanisms varied significantly and were not the same in each lake system. Hydrolysis was much more important for Lake Ontario than for Lake Pepin, especially for D4. Hydrolysis in sediment was not a significant loss process for any compound in either lake. Instead, the main net loss process for sediment was burial, which was especially important for D6. Although all three compounds are very volatile (log KAW > 2.5), the relative contribution of volatilisation to total losses was predicted to be limited in both lakes by the relative magnitude of other processes, sorption to organic phases in the water column and lake depth. Nevertheless, volatilisation is still predicted to be the most important loss process for D6 in Lake Ontario and is also responsible for more than 20% of all losses of D5 in both lakes. Model outputs were compared with observed concentrations in surface sediments and reasons for discrepancies discussed.

**EC05B-6**

**Continental scale inverse modeling of European River contaminants**

A Pistocchi[1], D Marinov[2], BM Gawlik[2]
[1]GECOsistema srl, CESENA, Italy
[2]EC JRC, ISPRA, Italy

We use a pan-European data set of measured river water concentrations of 16 common organic water contaminants, namely: Naproxen, Ketoprofen, Bezafibrate, Ibuprofen, Diclofenac, Gemfibrozil, Benzotriazole, Caffeine, Carbamazepine, Sulfamethoxazole, Methylbenzotriazole, Nonylphenolethoxy-1-carboxylate (NPE1C), Nonylphenol (NP), Bisphenol A, Estrone, Octylphenol (OP). We perform a back analysis of emissions and chemical half lives through a simple two-parameter inverse model. We identify for each chemical a set of Pareto-optimal or non-dominated pairs of half lives and emission factors that compare favorably with observations. Moreover, we derive log-linear regression equations to predict loads from an indicator of catchment population for each chemcial. On the basis of these equations it is possible to map continuous distributions in space of river concentrations and loads, therefore generalizing the results of a sampling campaign from discrete points, and enabling calculation of the total chemical loads to European seas, by considering the range of variability of emission factors and half lives.

**EC05C-1**

**Determination of nine native steroid hormones in biological (e.g. blood and tissues) and environmental (e.g. manure, soil and sediment) samples by GC-MS/MS**

M Hansen, NW Jacobsen, ST Mariga, FK Nielsen, E Björklund, KA Krogh, B Styrishave, B Halling-Sørensen
University of Copenhagen, Faculty of Pharmaceutical Sciences, COPENHAGEN, Denmark

The vertebrate steroidogenesis is a metabolic pathway responsible for production of important biological process (e.g. growth and reproduction). Many substances are today known as endocrine disrupting chemicals (EDCs), i.e. interfering with hormone homeostatics and the steroidogenesis [1]. Key steroid hormones are; pregnenolone, progesterone, dehydroepiandrosterone, androstenedione, testosterone, dihydrotestosterone, estrone, 17α-estradiol and 17β-estradiol.
Many (eco)toxicologists seek to investigate the effects of EDCs on a range of vertebrates, and thereby identify the need for detailed and systematic studies on interactions between the individual steroid hormones expressed in the steroidogenesis. A prerequisite for this is a reliable analytical methodology for the simultaneous determination of several steroid hormones in the investigated biological sample (e.g. blood, gonads, brain).
When steroid hormones are released into the environment, predominant from animal wastes and human waste water, they have an environmental impact, e.g. the feminisation of fish, amphibians and others [2-3]. Consequently, there is a need among environmental chemists and engineers to measure steroid hormones in environmental samples (e.g. manure, soil, sediment and water) to describe the fate of these compounds in nature and in waste treatment optimization processes.
This presentation outlines for the first time the development and application of an analytical method to determine nine steroid hormones in biological and environmental samples. The methodology has been applied to toxicological studies (e.g. in-vitro studies, in-vivo frog studies, and seal and polar bears blood plasma) and environmental studies (e.g. soil sorption, manure content, manure separation technologies, activated sludge studies). Attempts will be made to present some of these cases.

**The application of direct hollow fiber liquid phase microextraction for determining sludge adsorption of non steroid anti-inflammatory drugs during sewage treatment**

E Larsson, JÅ Jönsson
Lund University, LUND, Sweden

Non-steroid anti-inflammtory drugs (NSAIDs) are all consumed in large amounts in many countries and also belong to the pharmaceuticals most frequently detected in surface waters. Although they posses great similarities in physicochemical properties, studies show that ketoprofen are removed to a much lesser extent than ibuprofen during sewage treatment. This raises a number of interesting questions: Why do substances with such similar properties behave so differently under the same conditions? Ibuprofen is efficiently removed from the sewage water, but which are the main removal mechanisms? Is it totally degraded to carbon dioxide and water or non-toxic products or does a significant adsorbtion to the sewage sludge - which is often used as a fertlizer in crop production - take place during sewage treatment? How much of the total removal, in numbers, can be attributed to adsorption to sludge and where in the sewage treatment plant (STP) does the major adsorption in that case occur? The main purpose of this study is to investigate and quantify the removal due to sludge adsorbtion of the four aformentioned NSAIDs throughout the STP. This is performed by measurements of the NSAIDs in water as well as in sludge samples from the different steps of an STP. Analysis of such such complex samples poses high demandes on the analytical procedure. In this study hollow fiber liquid-phase microextraction (HF-LPME) is employed. The technique has several advantages over more classic extraction techniques, such as high enrichment, excellent clean-up, negligible consumption of organic solvent and simplicity in equipment and practical performance. It has also previously been successfully employed on digested sewage sludge slurry samples. Final analysis of extracts is performed by liquid chromatography quadrupole time of flight mass spectrometry (LC-MS Q-TOF). The method yields high enrichment factors (1 700 - 2 500 times) for extraction of the NSAIDs from influent water samples with apropriate sample dilution, giving overall MDL values of 0.04-0.11 ug/L for the different analytes and has also been successfully employed to biosludge samples. The study provides quantification of the sludge adsorption of four anti-inflammatory drugs throughout the sewage treatment process as well as a simple and environmentally friendly analytical method applicable for complex aquoeus as well as semi-solid samples.

**EC05C-3**

**Analysis of personal care products in German fish tissue by GC-MS/MS: a nationwide study**

S Usenko[1], B Subedi[1], CK Chambliss[1], BW Brooks[1], J Koschorreck[2]
[1]Baylor university, WACO, United States of America
[2]Umweltbundesamt, BERLIN, Germany

German Environment Specimen Bank (GESB) fish tissue samples, collected from fourteen different GESB locations, were analyzed for the twelve PCPs including fragrance materials, alkylphenols, photo initiators, and triclosan. The analytical method utilized pressurized liquid extraction (PLE) with in-cell silica gel clean-up, gel permeation chromatography (GPC), and gas chromatography ion-trap tandem mass spectrometry GC/MS-MS. Statistically-derived method detection limits (MDL) ranged from 1.2-37.9 ng/g wet weight. Galaxolide and tonalide, both synthetic polycyclic musk fragrances, were the most frequently detected PCPs. Galaxolide was detected in 13 out of 14 fish tissue samples whereas tonalide was detected in 9 out of 14 fish tissue samples. The maximum concentration of galaxolide (447 ng/g ww) and tonalide (15 ng/g ww) were measured in the Saar River at Rehlingen. Galaxolide and tonalide concentrations were positively correlated with percent lipid in fish tissue (r2= 0.711, p=0.001 and r2=0.769, p: less than 0.001, respectively). Triclosan was measured at or near MDLs only in the Elbe River at Blakensee and in the Donau River at Kelheim. PCPs were not detected in Lake Belauer.

**EC05C-4**

**The uptake of pharmaceuticals into aquatic organisms; the importance of species traits and exposure route**

J Netherton
Fera, YORK, United Kingdom

A wealth of information is now available on the occurrence and effects of pharmaceuticals in the environment, but our understanding of the uptake dynamics of pharmaceuticals through aquatic and terrestrial food webs is limited. The present study aimed to address this by:
- Comparing the uptake of pharmaceuticals into aquatic invertebrates with different traits, including the freshwater shrimp (Gammarus pulex), the water boatman (Notonecta glauca) and the freshwater snail (Planobarius corneus)
- Exploring the relationship between pharmaceutical physico-chemical properties and pharmacological properties and uptake into aquatic invertebrates
- Assessing the importance of the exposure route (water/dermal or food) in the uptake of pharmaceuticals into aquatic invertebrates
- Studying the trophic transfer of pharmaceuticals through a simple aquatic food chain

Using the radiolabelled pharmaceuticals carvedilol, fluoxetine, 5-fluorouracil, moclobemide, diazepam and carbamazepinebioconcentration factors (BCFs) for G. pulex ranged from 4.55-185900 and increased in the order moclobemide < 5-fluoruracil < carbamazepine < diazepam < carvedilol < fluoxetine. In N. glauca BCFs ranged from 0.13 - 1.60 and increased in the order 5-fluorouracil < carbamazepine < moclobemide < diazepam < fluoxetine < carvedilol. For P. corneus, the BCF for carvedilol was 57.3. The differences in uptake across the three organisms may be due to differences in organism size, mode of respiration and behaviour and the pH of the test system.
The relationships between VD and BCF were weak, strong correlations were found between Log Dlipw and BCF for both G. pulex and N. glauca.
When looking at the importance of exposure, the G. pulex data showed that the tissues concentrations in the G. pulex were significantly different for each exposure route for carvedilol and fluoxetine. The results indicate that uptake from dissolved chemicals from the water may be more important for accumulation in G. pulex than uptake from the food alone. However for N. glauca, the data show that the route of exposure of fluoxetine made a significant difference to the body burden of N. glauca. N. glauca took up less from the water compared to that assimilated from the food. Preliminary results show that fluoxetine can be transferred through three trophic levels of an aquatic food chain.

**Investigating the chlorination and by-products of pharmaceuticals by liquid-chromatogra-**

**phy-tandem mass spectrometry**
R Rodil, JB Quintana, R Cela
University of Santiago de Compostela, SANTIAGO DE COMPOSTELA, Spain
The fate of pharmaceuticals in the water cycle has received a strong attention during the last few years and particularly during wastewater treatment and drinking water preparation. However, most studies have considered just the elimination of these compounds without accounting for possible transformation processes. Indeed, this may result in an underestimation of possible environmental and health hazards, as transformations may in some cases even lead to the production of more toxic compounds. An example is the chlorination of the widely used analgesic acetaminophen, which produces the toxic benzoquinone. Thus, it is crucial to investigate the degradation routes of pharmaceuticals during chemical oxidations that are often employed for drinking water preparation. To identify the formed by-products, liquid chromatography-tandem mass spectrometry (LC-MS/MS) is particularly useful.
In this work, fifteen pharmaceuticals and metabolites have been treated with chlorine, the most common water disinfection chemical. After 24 h of reaction, it was quenched with ascorbic acid and the remaining pharmaceutical concentrations measured by LC-MS/MS. Under these relatively strong oxidation conditions, six of them (ibuprofen, ketoprofen, clofibric acid, fenoprofen, carbamazepine and bezafibrate) were found to be non-reactive. Subsequently, the reaction kinetics of the nine compounds that reacted with chlorine (phenazone, propyphenazone, atenolol, salbutamol, propanolol, diclofenac, naproxen, salicylic acid and indomethacine) were investigated in detail at different chlorine dose, pH and bromide concentrations by means of experimental design methodology. Also, several transformation products were tentatively identified by positive and negative electrospray LC-MS, in the scan mode, and LC-MS/MS, operated in product ion scan, with a hybrid quadrupole-time of flight instrument (QTOF). Finally, the by-products were investigated in real samples (surface and waste water) by SPE-LC-MS/MS.

## EC06 - Fate and exposure modelling including scenario analysis

### EC06A-1

**MACRO in FOCUS versus PEARL - do both models adequately describe groundwater exposure to pesticides under Swedish conditions?**
G Czub
Swedish Chemicals Agency, SUNDBYBERG, Sweden
Groundwater exposure is one of the critical endpoints in the risk assessment of plant production products, regulated in the European Union by the Directive 91/414/EEC. In Sweden, simulations with the model PEARL, one of the four pesticide leaching models applied in the EU, and the implemented scenario Hamburg is accepted unless the predicted environmental concentrations in groundwater (PECgw) exceed 0.01 µg/L, i.e. a threshold by a factor of ten below the regulatory limit. For higher PECgw, simulations with the model MACRO and three national Swedish scenarios are requested, which are more representative for the Swedish hydro-geological characteristics with macroporous soils and the cold climatic conditions. Aim of this study is to investigate deviations between the model predictions in dependence of the physical-chemical properties of the pesticides, and to evaluate the appropriateness of the safety factor of ten for acceptance of PEARL Hamburg simulations. Comparing simulations with both models have been performed for the treatment of cereals and pome fruits for 25 non-volatile hypothetical chemicals with varying combinations of half-lives (DT50) and organic-carbon partition coefficients (Koc) covering the relevant range of physical-chemical properties of pesticides. For the simulations with PEARL, which also considers volatilization as a dissipation pathway, additional 25 volatile chemicals with the same DT50- and Koc combinations were defined. In general, model simulations with PEARL yielded lower PECgw than simulations with MACRO and the Swedish scenarios. In particular volatile compounds showed by up to three order of magnitude lower concentrations. High macropore flow in the scenario Näsbygård resulted in a strong fluctuation of the magnitude of PECgw in dependence of the weather conditions and thus application time. For the protection of human health, conservative values should be considered as far as possible in the regulatory risk assessment of pesticides. Considering this approach, the simulation results suggest that for Swedish conditions, the model MACRO and the Swedish scenarios should be preferred for chemicals with a Koc above 100 L/kg. Moreover, for low DT50 (< 50 days) - low Koc chemicals (< 500 L/kg), model simulations for the scenario Näsbygård should be performed for several dates of initial application in order to avoid an underestimation of the leaching potential as a result of its sensitivity to weather conditions.

### EC06A-2

**Modelling approach to estimate emission of Plant Protection Products from protected crop systems to surface water in Mediterranean countries**
NA Suciu[1], M Egsmose[1], A Pardossi[2], AMA van der Linden[3]
[1]European Food Safety Authority, PARMA, Italy
[2]Università degli studi di Pisa Dipartimento di Biologia delle Piante Agrarie, PISA, Italy
[3]National Institute of Public Health and the Environment, BILTHOVEN, The Netherlands
A sector with relatively unknown impact on the environment is the horticultural sector. Greenhouse production is considered by the Regulation (EC) No 1107/2009 to prevent release of PPPs into the environment, contrary to field conditions. However water boards frequently measure the occurrence of PPPs and biocides in surface water near and in protected crop areas. In this study the FOCUS PEARL model was parameterized to perform simulations for Plant Protection Product (PPP) emissions from greenhouses to surface water, after application to a tomato crop. A comparison with the open field was made in order to investigate how the climatic conditions, which are more controlled under greenhouse conditions, influence the PPP emissions to surface water. Although only a limited number of runs were performed, the results show the existence of two hypothetical substances (subsequently indicated as CC and CC M) in the water drained from greenhouses, contrary to what is stated in the European Regulation (EC) No 1107/2009. The irrigation amounts given during the crop cycle and the temperature conditions within the covered structure have an important influence on PPP's emission as increasing the irrigation volume and/or decreasing the temperature result in increased concentrations of CC and CC-M in drainage water whereas the opposite occurs when the temperature is increased. Flushing the soil at the end of the crop cycle and irrigating with minimum water excess during the crop cycles, as an alternative to over-irrigation for the entire cultivation period, resulted in lower CC and CC-M leaching/drainage. However to generalise these findings, additional runs for other substances and other crops than tomatoes are required.

French higher-tier national scenarios were developed for field crops in order to support the registration of Plant Protection Products (PPPs) in France. The scenarios cover the most representative agricultural conditions in France and are implemented in a ready-to-use tool.
The scenarios consist of combinations of weather, soil, and crop parameters. France is divided into 31 Agricultural Units (AU). One MARS-tile is assigned to each AU, consisting of daily weather data. The selected tile represents the largest agricultural area within the AU.
Relevant soil types were identified and their area within each AU was calculated by INRA Orléans. In total 18 major representative soil types are considered with profile depths ranging from 40 cm to 140 cm.
The field crops sugarbeet, winter wheat, winter oil seed rape, grain maize, fodder maize, winter barley, potato, and sunflower are considered in the scenarios. They are not calculated as monoculture, but as realistic crop rotations (1-3 years). The selected rotations as well as the crop characteristics (such as emergence and harvest dates) are AU-dependent.
Depending on the occurences of the crops within the AUs and the possible combinations of soils and crops, different numbers of scenarios are available for the crops, ranging from 49 scenarios for potatoes to 289 scenarios for fodder maize.
The final endpoint used in the evaluation is the 90th overall percentile concentration, resulting from the combination of the 80th temporal percentile of each single scenario and the 80th spatial percentile from all scenarios together.
The scenarios are implemented in an ACCESS®-database, so that all parameters are stored in a transparent way and are fully accessible. A FROGS user interface is also available in order to enter the substance parameters and application scenarios, and prepare the relevant input files for PEARL 3.3.3 simulations, and process the PEARL 3.3.3 results for evaluation.
All the available options of PEARL 3.3.3 regarding substance and application parameters are also applicable in the FROGS tool. In addition, FROGS allows for input of the applications relative to BBCH growth stage, in full adequation with the intended use of the PPP. Output summaries, distribution graphs, and the final PECgw value for the parent substance and all metabolites are derived automatically by the FROGS-tool. Mitigation by location or soil properties is possible without the necessity of further scenario calculations.

### EC06A-4

**Short-term air-concentration variability: benefits of model integration**
M Morselli[1], D Ghirardello[2], M Semplice[2], A di Guardo[2]
[1]Universitry of Insubria, COMO, Italy
[2]University of Insubria, COMO, Italy
Several monitoring campaigns from different locations have shown how air concentrations of persistent semivolatile chemicals (SVOCs) can exhibit short-term (less than 24-hour) variations. In some cases, the observed patterns were ascribed to the variability of planetary boundary layer (PBL) height and structure. This aspect, which is widely known to influence the dispersion of pollutants emitted to atmosphere, is well accounted for in air dispersion (AD) models, which are well suited to describe single episodes of pollutant release and transport. Integrating the capabilities of such models into a multimedia fate box (MFB) modelling approach could thus offer important insights into the key processes that govern the short- and long-term behaviour of SVOCs. In the present work, a coupled meteorological preprocessor-MFB model previously developed by our research group is run to test its ability to capture the short-term variations observed in the PCB air concentrations measured in Zurich during a three-day period; a good model performance, with an agreement wich is generally within a factor of about 2-3, was observed. The fully-integratedy version of the model, which also incorporates an AD model based on the Gaussian equation, was then run for two PAHs, in order to assess the impact of an incinerator-like point source on the concentrations in air and soil. Results stressed the large influence exerted by PBL meteorology in determining the frequency and amplitude of the short-term variations in air concentrations and showed the magnitude of the potential increase in concentrations due to the point source. Further simulations showed the increased contamination of the soil environment due to the combination of low PBL height, precipitation and point source contribution and the extent of the consequent degassing episodes due to favourable atmospheric conditions (such as increased PBL heights and wind speed), which have the effect of "recharging" the lower air compartment.

### EC06A-5

**Modelling the cycling of persistent organic pollutants in shelf seas with a combined hydrodynamic and fate and transport ocean model: the North Sea system**
KTA O'Driscoll[1], T Pohlmann[1], B Mayer[1], T Ilyina[2], PE Damm[1]
[1]Universität Hamburg, Centre for Marine and Atmospheric Sciences, HAMBURG, Germany
[2]Max Planck Institute for Meteorology, HAMBURG, Germany
The environmental fate of selected persistent organic pollutants (POPs) in the North Sea is modelled with a combined hydrodynamic and Fate and Transport Ocean Model (FANTOM). Large amounts of POPs enter the North Sea system from the surrounding countries. Major entrance pathways of POPs to the North Sea are through atmospheric deposition and river inputs, with additional contributions coming from bottom sediments and adjacent seas. POPs in the ocean are subject to a wide range of processes including mechanical, chemical, physical, and biological processes. The fate of POPs in the oceans is not yet completely understood, though oceans are generally considered to act as ultimate sinks for POPs. Budgets of POPs are calculated to determine whether the North Sea can act as a reservoir of POPs. In this study, the POPs PCB 153 (almost insoluble in water) and lindane (gamma-HCH) (very soluble in water) are modelled for the period 1995 - 2005. A 3-D hydrodynamic model is a necessary prerequisite tool for modelling the fate of POPs in the ocean. For this purpose, we have developed a very high resolution version of the Hamburg Shelf Ocean Model (HAMSOM) for the North Sea region. The impact of climate variability on POP levels in the North Sea is investigated by performing future scenario model runs in 10 year time slices to the year 2100 using plausible POP input levels. Hydrodynamic variables are calculated in the HAMSOM which is forced at the surface and open boundaries. POP processes are calculated with the FANTOM model. Evolution of the total concentration of a pollutant at a fixed point is calculated with a simple Eulerian, advective-diffusive model

with sources and sinks. Atmospheric concentrations of POPs are provided by output from the atmospheric model of the MSC-E, EMEP. The net flux of a pollutant to the sea surface from the atmosphere is calculated as the net value of gaseous air-sea flux, dry particle deposition flux and wet deposition flux. POP concentrations in river estuaries have been calculated from available datasets. Results show that gamma-HCH concentrations are highest in summer but PCB 153 concentrations appear to be greatest during the winter months. Concentrations of PCB 153 and gamma-HCH decrease in the North Sea over the period 1995-2005. Preliminary results show that sediment concentrations also decrease during this period, suggesting that perhaps the North Sea cannot act as a reservoir of POPs for the oceans.

**EC06A-6**

**Development and validation of environmental fate model for herbicides of paddy fields using grid-catchment integrated multimedia modeling system (G-CIEMS) for all Japan area**

Y Imaizumi, N Suzuki, F Shiraishi, D Nakajima, S Serizawa, R Kamata, S Kageyama, J Kobayashi, T Sakurai, H Shiraishi
National Institute for Environmental Studies, TSUKUBA, Japan

We developed high accuracy model which could calculate daily concentration variation for many herbicides in all rivers in Japan. Monitoring data were actively used for representative chemical concentrations in environment for estimation of risk analysis. However, observed values have temporally-spatially specific information for limited numbers of chemicals. It is important to cover temporally-spatially variable concentration for many chemicals. So, model calculation should be applied, especially for ecological risk analysis. Pesticides are absolutely necessary. However, pesticides should be carefully controlled because of its original purpose of herbicidal, insecticidal, or fungicidal actions. Rice is a most major crop plant in Japan. Since schedules of rice transplanting collect to a specific period in each region, pesticides are also intensively used and run off to rivers. Herbicides are especially need to be regarded because these are thrown in paddy water and that why have high run-off ratio. For ecological risk analysis, it is important to calculate daily variation of pesticide concentrations in all rivers in Japan for many kinds of pesticides.

We had developed the multimedia environmental fate model G-CIEMS (Grid-Catchment Integrated Multimedia Modeling System) and Japanese GIS data set used for this model. In this study, we developed the method to predict daily variation of concentrations of many herbicides to paddy fields in all area in Japan. For developing the method, we collected, analyzed, and make a database of various kinds of relative information. We calculated daily emission amount of 26 kinds of herbicides for each river segment and air mesh, which data suitable for G-CIEMS model. In order to validate this model, we investigate herbicide concentrations in seven rivers in Japan. In total 182 pairs (= 7 river sites x 26 herbicides), herbicides were detected in 171 pairs that usable to the validation of this model. To evaluate the reliability of this model, peak concentration and peak days were compared between predicted variations and observed variations for 171 pairs of sites and herbicides. Peak concentration differences between predictions and observations were less than one order of magnitude in 113 pairs which reached 66% of total 171 pairs. Peak day differences between predictions and observations were less than two weeks in 136 pairs which reached 80% of total 171 pairs.

**EC06B-1**

**Guidelines for good modeling practice in environmental assessment of chemicals**

AM Buser[1], M Macleod[2], M Scheringer[1], D Mackay[3], K Hungerbühler[1]
[1]ETH Zurich, ZURICH, Switzerland
[2]Stockholm University, STOCKHOLM, Sweden
[3]Trent University, PETERBOROUGH, Canada

Multimedia models are increasingly used as scientific tools and in a decision-making context. One of the obstacles to more rapid and widespread adoption of models in risk and hazard assessment for chemicals is the lack of clear guidelines for applying them. Without such guidelines, model users may remain unaware of limitations, uncertainties, omissions and subjective choices in models. The risk is then that models are used for purposes different from those intended, making untenable conclusions possible. In order to stimulate the correct and careful use of models, the SETAC Exposure Modeling Advisory Group has taken the initiative to provide a set of clear *good modeling practice (GMP)* guidelines. The guidelines aim to serve as a reference for applying existing models for the environmental assessment of chemicals in a decision-making context.

The selection of an appropriate modeling tool is an essential requirement in the modeling process. Models under consideration should be examined for appropriate scope and domain of application, and their constraints and major assumptions. The proposed GMP guidelines emphasize the need to clearly document the identity and version number of the model that is used, as well as the values and sources of all input data. Any changes made to the default parameterization or model equations must also be clearly specified in the report. A comprehensible and complete documentation of the model results is crucial. Each result must be clearly associated with a corresponding set of input data. Model results should be clearly separated from interpretation and discussion. One of the goals of the GMP guidelines is to ensure that an interested third party can reproduce the modeling result. This will increase the transparency of decision-making processes that rely on model results. Recommendations for sensitivity and uncertainty analysis are also provided.

A hazard assessment of decamethylcyclopentasiloxane has been carried out as a case study to illustrate application of the good modeling practice guidelines.

**EC06B-2**

**Transfer of PCB from sediment to biota: development of a bioaccumulation model in a risk assessment perspective**

C Lopes[1], A Roy[1], H Persat[2], M Desmet[3], ME Perga[4], M Babut[1]
[1]Cemagref, LYON, France
[2]CNRS, LYON, France
[3]CNRS, Université Tours, TOURS, France
[4]INRA, THONON-LES-BAINS, France

Many chemical, physiological and trophic factors are known to be important in PCB bioaccumulation processes and trophic transfers in biota. Understanding the primary factors influencing PCB contamination of fishes is critical for predicting and assessing the risks to upper-trophic levels consumers including humans. We propose here (1) to identify PCB contamination pathways that could explain between and within species variability in fish concentrations; and (2) to describe PCB transfer along fish food chains. Three freshwater river fishes (Barbel, Bream and Chub) were sampled in three sites along the Rhone river (France), where fish consumption is partially prohibited for exceeding the current regulatory threshold. By combining stable isotope mixing models and stepwise regression, we showed that fish body size, PCB concentration in sediment and foraging habitat (exploitation of detrital carbon sources) explained around 80% of the within- and between species variability observed in PCB concentrations. Spatial gradients of contamination are more important than the type of food consumed and its trophic status. A bioaccumulation food-web model, based on physiological processes, was then developed in order to describe PCB transfer along the food chain of these fish species. Variation of environmental conditions (water temperature), individual physiological traits (growth rate) and physico-chemical properties of PCBs (Kow) are considered. We used Bayesian Inference to calibrate the involved functions, and we thus were able to pass on data variability and parameter uncertainty to model predictions and to provide a credibility interval around them. The predictions of our bioaccumulation model describes seasonal variations in fish PCB concentrations (due to environmental conditions) and appeared particularly efficient in a risk assessment perspective. By linking sediment to fishes contamination, our model could help in determining sediment management guidelines in the future.

**EC06B-3**

**Prioritising chemicals used in PCPs in China for environmental risk assessment: application of the RAIDAR model**

T Gouin, R van Egmond, J Mortimer, O Price
Unilever, SHARNBROOK, United Kingdom

Chemicals used in personal care products (PCPs) represent a significant fraction of chemicals used in commerce in China. Recently, there has been emerging concern regarding the use of a number of substances classified under this category, including the nitro- and polycyclic musks, UV blockers such as methylbenzylidene camphor, and preservatives such as the parabens. Unlike pharmaceuticals, PCPs, enter wastewater and the aquatic environment after regular use during showering or bathing. The environmental fate and effect datasets of many cosmetic ingredients, however, are limited. Methods for assessing environmental fate and prioritising chemicals used in PCPs are thus needed. In an effort to address this knowledge gap we have identified the chemical ingredients used in 2500 PCPs across China, and estimated the annual emission of these chemicals. An initial list consisting of approximately 1000 chemical ingredients from these products is identified and characterized. Next, the physical-chemical property data for these substances have been estimated, and used as model inputs in the Risk IDentification And Ranking (RAIDAR) model, which has been parameterized for the Chinese environment. The result from this ranking exercise is a list of chemicals for which risk assessment could be prioritized.

**EC06B-4**

**Cross-sectional trends in human body burdens with age? The role of atmospheric emissions.**

CL Quinn, F Wania
University of Toronto Scarborough, TORONTO, Canada

Body burdens from the cross-sectional biomonitoring of persistent bioaccumulative contaminants in a human population are often plotted against age. Typically in the literature, such cross-sectional relationships have been interpreted to provide information on longitudinal trends in human exposure. We used longitudinal trends in human exposure simulated with the CoZMoMAN model to calculate cross-sectional body burden versus age trends (CBATs) and to investigate the factors that control them. Our calculations indicate that CBATs can be categorized into three general shapes: dual maxima, adolescent minima, and rapid escalation. Each CBAT shape occurs at a characteristic time relative to the emissions profile. A population cross-section will exhibit the dual maxima profile during periods of increasing emissions. The adolescent minima will be observed during periods of decreasing emissions, and rapid escalation corresponds to periods after emissions have ceased but contamination of the environment remains. Many model input parameters, including chemical partitioning properties, metabolic degradation half-lives and the length of the emission period, have surprisingly little influence on the CBATs. The most important factor controlling the shape of cross-sectional time-trends is the amount of time elapsed since emissions have decreased. We propose that what many cross-sectional biomonitoring studies have interpreted as an increase in body burden with age is actually a result of sampling many decades after the peak in emissions occurred. As such, we propose that CBATs can be used as an indicator for the temporal trend of the emissions experienced by a given population. In other words, human biomonitoring studies can be used to reconstruct emission timelines. In some instances, the emission peaks reconstructed from human biomonitoring data occur earlier than current historical emission estimates suggest.

**EC06B-5**

**Increase of contaminant levels in the Arctic due to future climate change**

KM Hansen, J Brandt, LM Frohn, C Geels, A Gross, GB Hedegaard, CA Skjøth, AB Hansen, JH Christensen
National Environmental Research Institute, Aarhus University, ROSKILDE, Denmark

We have applied the Danish Eulerian Hemispheric Model (DEHM) to study the impact of climate change on contaminant levels in the Arctic. DEHM is a 3-D atmospheric chemistry-transport model developed over the last 20 years for studying the long-range transport of SO2, SO4, and Pb to the Arctic. The model covers the Northern Hemisphere and all important source regions for the Arctic are included in the model domain. This model has been developed further to include four chemical groups: a group related to ozone chemistry, a group related to primary particulates, a group with mercury species/chemistry, and a group with Persistent Organic Pollutants (POPs). The model has a spatially detailed 3-D atmosphere up to 15 km over the surface. In addition, it has four surface compartments: a 75 m thick ocean layer, a 15 cm thick soil layer, and dynamically evolving vegetation and seasonal snowpack compartments.

The model system has been run with meteorology obtained from ECHAM5/MPI-OM (SRES A1B scenario) for three different decades: 1990-1999, 2090-2099 and 2190-2199. In this climate scenario the global temperature is predicted to increase continually with 3 °C by the end of 2100 and 4.2 °C by the end of 2200 relative to the period 1971-2000.

The model system was run initially for a period in order to spin-up the concentrations of POPs in the ocean and soil compartments. The concentrations in air, ocean water and soil of all the species from this simulation where used as initial concentrations for three different model runs with constant emissions (from year 2000) for the decades: 1990-1999, 2090-2099 and 2190-2199 using input from the ECHAM5/MPI-OM climate model. The differences between the results for the three decades are hence only due to changes in the meteorological as predicted by the ECHAM5/MPI-OM model system.

The results produced with the DEHM model system indicates that the atmospheric concentrations of the studied POPs will increase due to increased atmospheric transport to the Arctic in a future warmer climate. This study has shown that it is useful to use meteorological output from climate models to investigate the exposure levels of contaminants under future changed climate conditions.

**EC06B-6**

**Assessing the potential implications of global climate change on human exposure to contaminants in the Arctic: opportunities & limitations**

JM Armitage, C Quinn, F Wania
University of Toronto (Scarborough), TORONTO, Canada
The influence of global climate change on the transport of organic contaminants to the Arctic and the long-term implications for human exposure is a complex issue. There are at least five broad categories of change to consider; i) chemical use and emissions ii) extent of contaminant delivery to the Arctic environment iii) processing of contaminants in the physical environment iv) processing of contaminants in the human food chain and v) changes in exposure due to alterations in the lifestyle of Northern communities. Climate model-based projections describing changes to the physical environment in the Arctic are available and were used as guidance in scenario development. The main goal of the study was to estimate/constrain the factor of change associated with potential alterations to the physical environment and other aspects identified above (e.g. dietary transition). Global-scale fate and transport simulations were undertaken using Arctic Contamination Potential ($eACP_{10}$), a model-derived output integrating long-range transport and accumulation in surface media (i.e. excludes mass in atmosphere), to estimate factors of change associated with different scenarios. Simulations coupling output from fate/transport models with human food web bioaccumulation models were also conducted to examine the influence of diet. Compensatory behaviour was found to be a recurrent theme throughout this investigation whereby a single parameter (e.g. temperature) or combination of parameters (e.g. temperature + primary productivity) can exert antagonistic effects that tend to dampen the response to alterations in the physical environment with respect to human exposure potential. For hydrophobic contaminants (i.e. octanol-water partition coefficient > 100 000), shifts in diet appear to represent the greatest potential for change in contaminant exposure. While long-range atmospheric transport potential and air concentrations in the Arctic may be enhanced under global climate change, contaminant amplification and exposure potential in surface compartments most relevant for humans may actually be reduced in comparison to contemporary conditions. However, the realism/representativeness of the modeling tools used is a major uncertainty underlying these conclusions. A more detailed and dynamic treatment of the cryosphere would be a particularly useful undertaking in the overall context of this study.

## EC07 - Integrated chemical and biological approaches for toxicant identification

### EC07-1

**Effects-directed analysis of contaminated sediments from the Sava River, Croatia**

M Ahel[1], S Terzic[1], J Loncar[1], I Mikac[1], R Zaja[1], I Senta[1], M Popovic[1], R Sauerborn Klobucar[1], KE Tollefsen[2], KV Thomas[2], T Smital[1]
[1]Rudjer Boskovic Institute, ZAGREB, Croatia
[2]Norwegian Institute for Water Research (NIVA), OSLO, Norway
The application of toxicity identification and evaluation (TIE) protocols for the toxicological characterisation of contaminated sediments showed that the majority of the observed adverse ecological effects were associated with toxic organic chemicals. Considering enormous number as well as chemical and toxicological diversity of organic contaminants, effects-directed analysis (EDA) represents the best available tool for the comprehensive assessment of hazardous chemical contamination in aquatic sediments. The aim of this paper is to present the results obtained in a case study carried out in the Sava River basin, Croatia. The analytical approach used for screening included a detailed characterisation of the collected samples, based on the combination of gas chromatography/mass spectrometry (GC/MS) and liquid chromatography/time-of-flight mass spectrometry (LC/Q-TOF). Ecotoxicity profiling of the investigated samples was performed using a battery of bioassays, including cytotoxicity, chronic toxicity, EROD activity; inhibition of the multixenobiotic resistance (MXR), genotoxicicity and estrogenic potential. The most pronounced effect, detected in the Sava River sediment, was CYP1A induction potential. It was predominately associated with the nonpolar fraction and polycyclic aromatic hydrocarbons were indicated to be responsible for the observed effect. However, other endpoints, such as algal toxicity and estrogenic potential, indicated comparatively higher importance of polar contaminants.

### EC07-2

**Integrated bioassay and chemical analysis of glucocorticoid and estrogenic activities in the rivers Rhine and Meuse**

CJ Houtman[1], R ten Broek[1], M Schriks[2], JA van Leerdam[2], P Stoks[3], SC van der Linden[4], RJCA Steen[1]
[1]The Water Laboratory, HAARLEM, The Netherlands
[2]KWR Watercycle Research Institute, NIEUWEGEIN, The Netherlands
[3]Association of River Waterworks RIWA, NIEUWEGEIN, The Netherlands
[4]BioDetection Systems, AMSTERDAM, The Netherlands
Effect-directed analysis (EDA) has shown to be a valuable approach to investigate the nature of biologically active compounds. Various research groups have succesfully applied EDA and identified compounds responsible for endocrine disrupting, especially estrogenic, effects. However, many other hormone-like compounds are excreted naturally or are used as pharmaceuticals and thus might enter the environment via similar routes as estrogens. Indeed, using novel CALUX bioassays for progestagenic, androgenic estrogenic and glucocorticoid receptor activation, the presence of especially glucocorticoid activity in Dutch surface waters and glucocorticoids in waste water was recently reported. However, data on glucocorticoid activity remained scarce and its chemical identity in surface water unknown.
We investigated the presence and identity of glucocorticoid and estrogenic activities in the Dutch catchments of the main rivers Rhine and Meuse. GR and ER CALUX measurements were done throughout the year and at five different locations to investigate spatial and seasonal differences. Having experienced that natural and synthetic hormones often explain the majority of endocrine activities in aquatic samples, we decided not to perform a full EDA, but first to develop and apply specific and very sensitive target analysis methods on LC-LTQ-FT-orbitrap MS and UPLC-tQ-MS for a large number of natural and pharmaceutically used steroid hormones (estrogens, glucocorticoids, androgens, progestagens). The methods were used to analyze bioactive samples and to calculate the extent to which natural and synthetic hormones were responsible for the measured activity. GC-screening was applied to obtain a more integrated picture of the contaminant composition of the samples.
Glucocorticoid and estrogenic activities were detected at all locations and followed a seasonal pattern. Estrogenic activity was found in higher concentrations in the Meuse than in the Rhine. Glucocorticoid activity in waste water ranged between 0.01 and 0.6 µg dex-eq/L. Analytical methods were developed for over 30 steroid hormones. In waste waters, glucocorticoid activity was predominantly explained by cortisol, cortisone, prednisone, prednisolone and triamcinolone acetonide. The results in surface waters will also be discussed. GC-screening demonstrated the presence of complex and location specific mixtures of e.g. pesticides, pharmaceuticals, industrial solvents and flame retardants.

### EC07-3

**Structure elucidation of mutagenic contaminants in blue rayon extracts of river water**

M Krauss[1], C Gallampois[2], E Schymanski[3], W Brack[4]
[1]Helmholtz Centre for Environmental Research, LEIPZIG, Germany
[2]Helmholtz Centre for Environmental Research - UFZ, Permoserstr. 15, LEIPZIG,, Germany
[3]UFZ Helmholtz Centre for Environmental Research, LEIPZIG, Germany
[4]UFZ - Helmholtz Centre for Environmental Research, LEIPZIG, Germany
We elucidated the structure of mutagenic compounds in water samples using effect-directed analysis (EDA) based on a combination of (i) chemical fractionation, (ii) mutagenicity testing, and (iii) chemical analysis. Blue rayon passive samplers preferentially adsorbing planar aromatic compounds were exposed in the Elbe river downstream of discharges from dye industries. The blue rayon extracts were separated into acidic, neutral and basic fractions using cation and anion exchange cartridges and fractionated further by LC using a polymeric C18 column and subsequently a phenyl-hexyl column. The Ames fluctuation assay with strain TA98 was used to screen samples for mutagenic compounds with and without metabolic activation. Fractions showing the highest mutagenicity were analyzed by LC-MS/MS using a high resolution/high accuracy LTQ Orbitrap. Chromatograms were deconvoluted using the software MZmine and full scan and product ion mass spectra of intense peaks were submitted to molecular formula generation using the software MOLGEN-MSMS. To assign a structure to the molecular formulas, a database search in ChemSpider was combined with structural classifiers such as MS/MS fragmentation interpretation. High mutagenicity was found predominantly in the neutral and acidic farction. Based on the accurate mass measurement and isotope abundances a unique molecular formula could be assigned to almost all of the peaks of interest in the two LC-sub-fractions of the neutral fraction showing the highest mutagenicity. The structure elucidation from molecular formulas was the most critical step, but a range of compounds could be tentatively identified and confirmed by reference standards. Many other polyaromatic compounds yielded a low number of characteristic MS/MS fragments. Furthermore, often a large number of possible structures for the same molecular formula were retrieved from the Chemspider database. Thus, refined analytical approaches to include additional structural classifiers were investigated: A. comparison of ionization efficiencies in ESI and APCI in positive and negative ion mode for a range of reference standards suggests that these may be a useful classifier to suggest the presence of certain functional groups The use of deuterium exchange experiments and chemical derivatization was studied as a complementary approach to selectively confirm or rule the presence of functional groups.

### EC07-4

**Characterisation of dioxin-like compounds in road-side snow**

M Muusse[1], G Cornelissen[2], K Hylland[3], K Langford[1], KE Tollefsen[1], P Haglund[4], KV Thomas[1]
[1]NIVA, OSLO, Norway
[2]Norwegian Geotechnical institute, OSLO, Norway
[3]University of Oslo, OSLO, Norway
[4]University of Umeå, UMEÅ, Sweden
Snow is a useful tool to measure the accumulation of contaminants because it scavenges pollutants from the air due to its large specific surface area. In the current study volatile and non-volatile dioxin-like contaminants were identified in snow samples using an effect-directed analysis (EDA) approach.
Snow was collected in Oslo, the capital of Norway and one background sample was collected in a mountain area. The samples were filtered and extracted using solid phase extraction. The particles on the filters were extracted using accelerated solvent extraction, cleaned-up on a multilayer silica gel column and separated in 2 fractions: the hexane fraction F1 and the DCM fraction F2. In addition a subsample of the particles was analysed for black carbon (BC) content. Both the water fraction and the two particle fractions were analysed for AhR agonists using the CALUX assay and by GC-HR-ToF-MS for broad-spectrum analysis and to target for PAHs.
The AhR agonist levels in the water fractions from the city samples were between 15-387 pg/l. An elevated AhR activity of 221pg/l TEQCALUX was detected in the mountain sample. In the F1 particle fraction, where dioxins, furans and PCBs elute, TEQCALUX was <LOD. In the F2 particle fraction, where PAHs elute, TEQCALUX was between 1354-7389 pg/l.
One possible explanation for the elevated levels in the water fraction of the mountain sample could be the occurrence of BC in the samples collected in the city. All samples except the mountain sample were filtered before analysis. Dioxins and other contaminants are known to bind to BC and BC could possibly trap part of the contamination originally present in the snow, this could result in lower AhR agonist levels in the water fractions of the filtered city samples.
With targeted analysis of PAHs 0.0008-0.04% and 2-9% of the TEQCALUX could be explained in the water fractions and the particle F2 fractions respectively. This highlights the fact that there are other unknown AhR agonists present in these samples. Preliminary results from the GC-HR-ToF-MS showed a large amount of aromatic unresolved complex mixture (UCM) in the particle F2 fraction. Ongoing work utilising comprehensive gas chromatography coupled to mass spectrometry (GCxGC ToF MS) is focused on teasing out AhR agonists in this aromatic UCM. Further work will focus on more advanced broad-spectrum analytical techniques.

### EC07-5

**Effects - directed identification of novel antiandrogenic contaminants in fish exposed to wastewater effluents**

P Rostkowski[1], J Horwood[1], CR Tyler[2], P Behnisch[3], H Besselink[3], EM Hill[1]
[1]University of Sussex, BRIGHTON, United Kingdom
[2]University of Exeter, EXETER, United Kingdom
[3]BioDetection Systems BV (BDS), AMSTERDAM, The Netherlands
The widespread occurrence of feminized male fish downstream of some wastewater treatment works has led to substantial interest from ecologists and public health professionals. A survey of UK waste water treatment works (WwTWs) has revealed that the majority of the effluents sampled contain antiandrogenic as well as estrogenic activity[1]. Another study has demonstrated that feminization of fish was correlated with their predicted exposure to both antiandrogens and estrogens or to antiandrogens alone[2]. Identification of key active compounds in wastewaters is difficult as they can often be present at subnanogram per litre concentrations. However, a wide range of xenobiotics can bioconcentrate in fish bile at concentrations tens of thousands greater than in the effluent itself, facilitating the structural identification of bioavailable contaminants present in the ambient environment [3]. In this study, bile from fish exposed to a WwTW effluent was analysed for antiandrogenic contaminants using a bioassay-directed analytical approach. Fractionated bile was interrogated for anti-androgen activity using yeast and a mammalian-based androgen receptor transcription assay (Anti-YAS) and (AR-CALUX). Fractions containing

antiandrogen activity were analysed by gas chromatography- mass spectrometry (GC-MS) after trimethysilylation and the identities of key structures present in wastewater effluent have been determined. Key compounds identified included triclosan (a biocide- thought to act as a weak estrogen [4]) and chlorophene (a germicide not previously recognized as and antiandrogen). Other novel antiandrogenic compounds identified included: chloroxylenol (an antiseptic), resin acids, metabolites of pyrene and biphenyl, and compounds known as xenoestrogens: nonylphenol and bisphenol A. Together, triclosan and chlorophene accounted for >50% of the total antiandrogenic activity in fish bile and these compounds are currently being tested for antiandrogenic activity in vivo in fish.

[3]Institute for Environmental Studies (IVM), Vrije Universiteit, AMSTERDAM, The Netherlands

[4]Norwegian Polar Institute (NPI), TROMSØ, Norway

[5]The Norwegian School of Veterinary Science, OSLO, Norway

Endocrine disrupting compounds (EDCs) released into the environment may bioaccumulate and biomagnify in the foodchain. Significant concentrations of thyroid hormone-like (TH-like) compounds were found in biological tissue (e.g. in fat and blood) of top predators such as humans and polar bears (Ursus maritimus). This study aims to identify TH-like compounds in plasma of polar bear cubs-of-the-year by Effect-Directed Analysis (EDA) using a dedicated plasma sample treatment method.

Ion exchange solid-phase extraction (SPE) followed by liquid-liquid extraction (LLE) was evaluated by known TH-like compounds (hydroxylated polychlorinated biphenyls (OH-PCBs), hydroxylated polybrominated diphenyl ethers (OH-PBDEs), other halogenated phenols (OHPs) and perfluorinated compounds (PFCs)) as well as the less potent non-hydroxylated parent compounds of the PCBs and PBDEs spiked to cow plasma. Good chemically determined recoveries were obtained for OHPs, OH-PBDEs, OH-PCBs extracted from spiked plasma (>90%) and lower recoveries for PFCs (~60%) and for PCBs and PBDEs (~30%). In the radioligand T4*-TTR binding assay the spiked extracts showed TTR binding potencies which were in good agreement with the calculated theoretical spiking levels.

Then the SPE-LLE method was successfully applied to polar bear plasma samples in collaboration with the Norwegian University of Science and Technology (NTNU) and the BearHealth-project and the extracted samples were screened in the T4*-TTR binding assay. Measured TH-like activities were generally higher than the estimated activity based on the measured concentrations of target TH-like compounds. Three samples have been selected for further analysis, where the analyzed target compounds could only explain part of the measured TH-like activity, to identify the compounds causing the remaining activity. Identification studies will be carried out to explain the remaining TH-like activity.

## EC08 - Tracking community consumption of illicit drugs and other substances by measuring human metabolic residues in urban wastewater

**EC08A-1**

**Sewage epidemiology: potential of a novel approach**

E Zuccato, S Castiglioni

Mario Negri Institute, MILAN, Italy

Sewage epidemiology is a new approach to population studies, which use wastewater analysis for assessing collective voluntary and involuntary exposure of the members of a community to a wide range of chemicals. The rationale of this approach is that traces of almost everything we eat, smoke, drink, ingest, or absorb, are excreted with our urine or stool and end up in wastewater, where they can be measured.

Illicit drugs were the first application: residues of the drugs consumed by a collectivity are excreted in wastewater and their levels, knowing kinetic, metabolism, and behaviour in wastewater, and characteristics of the sewage system, can be used to back-calculate for the type and amount of the substances collectively consumed by the population.

However, this approach has a much wider range of potential applications. This include for instance pharmaceuticals. We know the amount of a given drug which is prescribed or sold in a given area, but we don't know the amount really taken by patients. Wastewater analysis for the metabolites of the pharmaceuticals can help in elucidating the compliance to the treatment, thus contributing to evaluate its efficacy. Other examples include pesticides, PCBs and food contaminants. Monitoring of the metabolites of these substances in wastewater is a new approach to estimate the real exposure of the population to these chemicals.

Sewage epidemiology needs a multidisciplinary approach, with the interaction of experts of several different fields, such as pharmacokinetic, medicine, and analytical chemistry. Monitoring wastewater has the potential to extract useful epidemiological information from qualitative and quantitative profiling of biological indicators entering the sewage system, and to become a useful tool to be used in population studies .

**EC08A-2**

**The overlooked importance of sampling to advance wastewater analysis from a promising method to a useful and reliable tool for the estimation of illicit drug abuse**

C Ort[1], AJ Brewer[2], C Banta-Green[3], J Field[2]

[1]The University of Queensland, BRISBANE, Australia

[2]Oregon State University, Department of Environmental Toxicology, CORVALLIS, OREGON, United States of America

[3]University of Washington, Alcohol and Drug Abuse Institute, SEATTLE, WASHINGTON, United States of America

Sewers were not designed to assess illicit drug consumption. However, immense advances in analytical chemistry have propagated wastewater analysis as a promising tool to tackle this difficult task. It has been shown for legal drugs that traditionally applied sampling methods are prone to systematic biases and random errors resulting in sampling artefacts ranging from "not significant"to "100% or more". For the first time we present illicit drug concentrations and loads at high temporal resolution in sewers to emphasise the importance of sampling. A unique time series at two-minute time intervals for 11 legal and illicit drugs and selected metabolites reveals high short-term fluctuations. Based on this and previous studies, we provide general recommendations for sampling in any catchment to make the wastewater epidemiology method a reliable and acknowledged tool in the future. Sampling is the first and most crucial step to maximise data quality. Sophisticated chemical and statistical analyses simply cannot make up for any deficiencies in sampling. If traditional sampling methods are not adapted to sample for illicit drugs, the wastewater epidemiology method may not be more accurate and reliable than traditional surveys and interviews.

**EC08A-3**

**The significance of chirality of illicit drugs for the estimation of drugs abuse using the sewage epidemiology approach**

B Kasprzyk-Hordern[1], DR Baker[2]

[1]University of Bath, BATH, United Kingdom

[2]University of Huddersfield, HUDDERSFIELD, United Kingdom

Most illicit drugs are chiral compounds. Their enantiomers reveal different potency and are often characterised by stereoselective disposition in the body. Amphetamines for example are characterised by one asymmetric carbon centre and exist in the form of two enantiomers, which significantly differ in potency, e.g. S(+)-amphetamine has twice as high stimulant activity as R(-)-amphetamine. However, R(-)-amphetamine has been reported to be as effective as the S(+)-enantiomer in the development of the psychotic syndrome. The phenomenon of the chirality of amphetamine is crucial in forensic identification of its illicit use. This is because amphetamine has some limited therapeutic use in narcolepsy and attention deficit hyperactivity disorder. Amphetamine is also formed as a metabolite of methamphetamine and several prescription drugs such as selegiline.

The aim of this presentation is to raise awareness of the importance of the phenomenon of chirality in forensic estimation of drugs abuse via sewage epidemiology approach. The report will present results obtained during a ten month long monitoring programme of several WWTPs in the UK. To the authors' knowledge this is the first report tackling the phenomenon of chirality in the estimation of drugs use using a sewage forensics approach. Among the studied chiral drugs are: amphetamine, methamphetamine, MDMA, MDEA, MDA, ephedrine and pseudoephedrine. The monitoring programme revealed that these chemicals are not released into wastewater in the form of racemic mixtures. It was for example observed that in the case of amphetamine, R(-)-enantiomer was dominant in all analysed wastewater samples. It was also noted that enantiomeric ratios of amphetamine enantiomers differed significantly between sampling points and sampling times and varied from 0.53 to 0.84. Similar patterns were observed in the case of other studied chiral drugs. There are several possible reasons for this behaviour. Among them are: (i) different metabolism patterns of enantiomers of the same drug with preferential metabolism of one enantiomer only, (ii) formation of illicit drugs as a result of metabolism of legally prescribed drugs, or (iii) use of drugs in non-racemic forms of drugs. Although a complex and demanding process, the verification of enantiomeric ratios can provide vital information about patterns of drugs usage and can help in the differentiation between their legal and illicit usage.

**EC08A-4**

**Analysis and interpretation of specific ethanol metabolites in sewage effluent for the quantitative measurement of regional alcohol consumption**

J Reid[1], K Langford[1], J Mørland[2], KV Thomas[1]

[1]Norwegian Institute for Water Research, OSLO, Norway

[2]Norwegian Institute of Public Health, OSLO, Norway

Ethyl sulphate and ethyl glucuronide are excreted in urine following the ingestion of alcohol and are useful biomarkers for the identification of acute alcohol consumption. The present study reports a novel ion-exchange mediated chromatographic method for the quantitative measurement of ethyl sulphate and ethyl glucuronide in sewage effluent, and presents a novel calculation method for the purposes of relating the resulting sewage concentrations with rates of alcohol consumption in the general population. Sewage samples were collected from a sewage treatment plant servicing 500 000 people over a 25 day period and analysed for levels of ethyl sulphate and ethyl glucuronide. The resulting data were then used to estimate combined alcohol consumption rates for the region, and the results compared with alcohol related sales statistics for the same region.Ethyl glucuronide was found to be unstable in sewage effluent. Ethyl sulphate was stable and measurable in all samples at concentrations ranging from 2 μg/L to 31 μg/L. The highest concentrations of the alcohol biomarker were observed during weekend periods. Sixty one percent of the total mass of ethyl sulphate in sewage effluent corresponds to alcohol consumption on Friday and Saturday. Sales statistics for alcohol show that consumption in the region is approximately 6750 kg/day. The quantity of ethyl sulphate passing through the sewage system is consistent with consumption of 4900 - 7800 kg/day.Sewage epidemiology assessments of ethyl sulphate can provide accurate estimates of community alcohol consumption, and detailed examination of the kinetics of this biomarker in sewage streams can also identify time-dependent trends in alcohol consumption patterns.

**EC08A-5**

**Trace analysis of barbiturates in wastewater by HPLC-LTQ-Orbitrap MS**

E Emke, R Helmus, P de Voogt

KWR watercycle research institute, NIEUWEGEIN, The Netherlands

In a recent survey, illicit drugs and their degradation products were encountered throughout the water cycle in the Netherland. There was also evidence for the occurrence of at least three barbiturates (barbital, pentobarbital and phenobarbital) in the water cycle. However, the method applied suffered from a lack of sensitivity for these compounds. Earlier research has confirmed that barbiturates are persistent in an aqueous environment and originate probably from leachates of old landfills [1]. There are almost 2500 different kinds of barbiturates known/synthesized from which only a few are ever used for medical purposes. Due their adverse side effects barbiturates are nowadays mostly replaced by other products like benzodiazepines. During the 1930s, barbiturates were used as sedatives but during the 1960s their illegal use became more and more widespread. In the Netherlands barbiturates are nowadays mainly in use as veterinary euthanasia

and antiepileptics. In 2009 the total amount of barbiturates imported in the Netherlands was 2068 kg. The largest part being pentobarbital 1296 kg followed by phenobarbital with 753 kg and barbital with 9.58 kg. Another source of phenobarbital is as the metabolite of primidone. The total prescription of Primidone in The Netherlands was 171 kg in 2007.
The first objective of our study was to set up a method to determine barbiturates in aqueous matrices with an increased sensitivity and accuracy. Secondly, we investigated the presence of barbiturates in wastewater. Finally we back calculated the total consumption of barbiturates and compared it with the import and export figures of the national inspectorate of the Netherlands

**Use of legal and illegal drugs in communities: methodological considerations for generating annual estimates of drug excretion based upon municipal wastewater sampling**
CJ Banta-Green[1], AJ Brewer[2], C Ort[3], JA Field[2]
[1]University of Washington, SEATTLE, United States of America
[2]Oregon State University, CORVALLIS, United States of America
[3]University of Queensland, BRISBANE, Australia
Municipal WWTP based testing for medications and drugs of abuse is in its infancy. The ability to document the presence of substances has been shown repeatedly around the world, however the utility of these data is limited until we understand how to reliably gather samples (e.g. for annual estimates) and accurately interpret results accounting for variability.
To address these methodological issues we undertook a year long, weekly sampling campaign in 18 cities in the Northwest region of the United States. Diverse municipalities were chosen for their variable population size, commuting flows, weather and resident characteristics. Data resulting from more than 900 tested samples provide insights into how to design sampling plans that account for day of the week, and longer periods, for stimulant drugs of abuse and opioid pharmaceuticals. Variability in data, and resulting confidence in the results, was found to be impacted by the specific compound of interest, the type of composite sampling utilized by WWTPs and the population characteristics of the municipality.
Determining sewer derived population estimates for drugs excreted appears to be a worthwhile endeavor and has the potential to provide data of sufficient quality to inform practice and policy decisions. However, it does have limitations due to variability that limits the precision of estimates. This variability differs for specific compounds based upon the chemical properties of the compound as well as the consumption pattern(s) for a community. Additionally, community characteristics and the WWTPs' methods for generating 24 hour composite samples influence index loads and variability. Future sewer based community estimates of drug excretion should be explicit about how samples were obtained. Researchers should also be explicit about the variability of estimates and ensure that variability is accounted for when making conclusions about the level or trends in substance use.

**EC08B-2**
**Illicit drugs in prisons: sewage epidemiology to evaluate use and trends**
C Postigo[1], N Mastroianni[1], M López de Alda[1], D Barceló[2]
[1]Institute of Envrionmental Assessment and Water Research, BARCELONA, Spain
[2]Catalan Insitute for Water Research (ICRA), GIRONA, Spain
The prevalence of illicit drug use and drug related problems in prisons has been widely reported. Different strategies for drug detoxification and rehabilitation and to prevent drug entry in prisons are carried out by penitentiary authorities worldwide. Evaluation of success of such programs requires fast and economic tools to monitor illicit drug use by prisoners. In this context, the present work applied the sewage epidemiology approach to assess for the first time drug abuse in a penal complex from the levels of different drug residues measured in the prison sewage waters and evaluated the suitability of this approach to track and control illicit drug usage in such facilities. Drug residues were measured in sewage waters with an analytical method based on on-line solid phase extraction-liquid chromatography-tandem mass spectrometry. Levels of consumption indicators measured in these waters were used to backcalculate drugs usage in the penal complex. Daily use was observed for methadone (13.7 $g.day^{-1}$ on average), ephedrine (4.0 $g.day^{-1}$ on average), cannabis (3.4 $g.day^{-1}$ on average), cocaine (1.1 $g.day^{-1}$ on average) and alprazolam (0.5 $g.day^{-1}$ on average). Sporadic consumption was observed for heroin, amphetamine, methamphetamine, and ecstasy. Additionally, illicit drug use in the prison was compared to illicit drug consumption results obtained with the sewage epidemiology in different cities in Spain, and with extrapolated illicit drug use data at national level. In spite of the fact that the sewage epidemiology approach applied may suffer from bias that still need to be investigated and refined, it provides near 'real-time' information on collective drug use in an anonymous way and constitutes a very useful, economic and fast tool to evaluate the efficiency of measures adopted to control and track drug abuse in this type of facilities (or any other provided that it has an STP associated or an accessible collector system).

**EC08B-3**
**Estimation of illicit drugs consumption by wastewater analysis: a five years-long investigation in Italy**
S Castiglioni, R Bagnati, M Melis, E Zuccato
Mario Negri Institute for Pharmacological Research, MILAN, Italy
Wastewater analysis is a novel tool to estimate drug consumption in a population, this method is based on the direct measurement of illicit drugs residues (parent compounds or urine metabolites) in urban wastewater, and the back-calculation of the local drug consumption from the measured levels.
The aim of this study was to investigate the pattern of drug consumption in Italy by wastewater analysis. Drug residues were measured in urban wastewater using a specific multiresidue analytical method based on LC-ESI-MS/MS. Drug consumption was then estimated from the measured levels considering wastewater flow rate, human metabolism and the average dose of each substance. Daily wastewater samples were collected in large and small cities in northern and central Italy, and a five years-long investigation was conducted in Milan. The weekly consumption profiles were similar in all the cities showing an increase in cocaine and amphetamines consumption over the weekend, and a stable consumption of cannabis and heroin through the week. Cannabis was the most used drug (20-33 doses/d/1000inhabitants), followed by cocaine (2-6 doses/d/1000inhabitants), methamphetamine (0.1-4 doses/d/1000inhabitants) and heroin (1-4 doses/d/1000inhabitants). These estimates were generally in line with the national prevalence data from epidemiological studies, furthermore they highlighted local differences in the patterns of consumption. In fact, cocaine and methamphetaminuse were mostly used in large cities, while heroin in smaller cities. The monitoring of drug consumption in Milan from 2006 to 2010 allowed the identification of several changing habits. Cocaine consumption in Milan was 1100 g/d in 2006-2008, but fell to 620 g/d in 2009 and remained stable in 2010. Heroin consumption dropped as well from 80 to 40 g/d in 2008-2009, while methamphetamine consumption rose from 15 to 130 g/d from 2006 to 2010. Daily cannabis consumption was stable (3100-3500 g/d) along all the investigated period. This study confirmed wastewater analysis as a suitable tool to produce objective and updated estimates of drug consumption in a defined population, being therefore able to complement epidemiological studies.

**EC08B-4**
**The consumption of illicit drugs in Brussels (Belgium) through sewage epidemiology**
ALN van Nuijs[1], JF Mougel[2], I Tarcomnicu[1], L Bervoets[1], R Blust[1], PG Jorens[1], HMG Neels[1], A Covaci[1]
[1]University of Antwerp, WILRIJK, Belgium
[2]Aquiris, BRUSSELS, Belgium
A one year sampling campaign of influent wastewater samples (235 samples in total) was set up in the largest wastewater treatment plant (WWTP) in Belgium, receiving wastewater from the largest part of Brussels. The consumption of cocaine (COC), amphetamine (AMP), methylenedioxy-methamphetamine (MDMA), methamphetamine (METH), methadone (MTD) and heroin (HER) in Brussels was evaluated based on measured concentrations of the parent compound and/or metabolites in daily 24-hour composite influent wastewater samples. The inevitable back-calculations used in the sewage epidemiology approach were adapted to newly available information. When a degradation of the compounds in wastewater was observed, the measured concentrations were corrected for this degradation to overcome underestimations. Further, new insights in excretion patterns of illicit drugs has led to adapted correction factors used in the back-calculations. For COC, three different back-calculation approaches were evaluated; based on benzoylecgonine (BE) or ecgonine methyl ester (EME) alone or on BE and EME together. No significant differences between the different back-calculations were observed. In addition, for the first time, efforts were made to calculate the number of inhabitants living in the catchment area of the WWTP in a real-time and dynamic way, based on concentrations of nitrogen, phosphorus, chemical oxygen demand and biological oxygen demand in the influent wastewater samples. Clear variations in the amount of inhabitants in the catchment area of the WWTP were observed, emphasizing the need for real-time calculations of this parameter instead of using the design capacity of the WWTP. For COC, AMP and MDMA a significant higher use during the weekend and holiday periods was observed ("recreational character") while for HER and MTD no trend in their consumption could be found. METH consumption was negligible. Generally, the sewage epidemiology calculations were in agreement with official statistics, when available. This study shows a further refining of the sewage epidemiology approach which leads to more reliable results. Because of the extensive sampling campaign, a sound evaluation of the results could be made. The approach shows great potential and in the future more efforts should be devoted to further optimize this methodology.

**EC08B-5**
**Illicit drugs in Canadian municipal wastewater and estimates of community drug use**
V Yargeau[1], K Tindale[2], H Li[2], A Rodayan[3], C Metcalfe[2]
[1]McGill University, MONTREAL, Canada
[2]Worsfold Water Quality Center, Trent University, PETERBOROUGH, Canada
[3]Department of Chemical Engineering, McGill University, MONTREAL, Canada
In this study we evaluated the distribution of selected drugs of abuse (cocaine and its major metabolite, benzoylecgonine (BE), amphetamine, methamphetamine and ecstasy (i.e. MDMA)) in municipal wastewater from three Canadian cities, and we estimated community drug use from the levels of these compounds in untreated wastewater. This is the first study to evaluate community drug use in cities from North America, and the comparison provided on previously published data from European cities provide some valuable insights into differences between North America and Europe in drug usage. Cocaine was the most widely used illicit drug at a median level for the 3 cities of 15.7 doses per day per 1,000 people. For the other drugs, the median doses per day per 1,000 people were 1.8 for amphetamine, 4.5 for methamphetamine and 0.4 for ecstasy. Methamphetamine use was highest in the largest city and cocaine use was lowest in the smallest city. In addition, data obtained on the removals of illicit drugs during wastewater treatment, generally >50% except in a WWTP that uses primary treatment, show interesting comparisons to European data where more advanced technologies are typically used to treat wastewater.

**EC08B-6**
**Estimation of illicit drug consumption via wastewater analysis in South-East Queensland, Australia: uncertainty evaluation**
FY Lai[1], C Ort[2], C Gartner[3], S Carter[4], J Prichard[5], P Kirkbride[6], R Bruno[7], G Eaglesham[4], JF Mueller[8]

[7]School of Psychology, University of Tasmania, HOBART, TAS, Australia
[8]University of Queensland, National Research Centre for Environmental Toxicology, COOPERS PLAINS, QLD, Australia
Illicit drug use is an important public health and social problem. Analysis of wastewater for estimating drug use has become a useful tool to estimate drug consumption at a community level. A key potential application of this tool is the assessment of changes in illicit drug consumption in a given population. However, the successful application relies on understanding the uncertainties associated with all aspects of the measurement. The uncertainties include sampling ($U_S$), flow measurement ($U_F$), chemical analysis ($U_C$), population size ($U_P$) and excretion fraction ($U_E$) and biodegradation in sewers ($U_B$) of a given drug. It is relatively easy to accurately estimate and

thus reduce US and UC compared to UP and UB. Researchers also need to rely on operators at sewage treatment plants (STPs) to obtain best available estimates for $U_F$. The aims of our study were to (a) reduce the sampling uncertainty through an optimized sampling method, (b) identify and evaluate the total uncertainty associated with our per capita drug consumption estimates, and (c) provide an estimation of illicit drug consumption over 12 days in a urban catchment from South East Queensland, Australia. We predicted our estimates having a remaining uncertainty in a range from 24 - 31% even with the best sampling practice and current chemical analysis. Apparently, the respective uncertainties, particularly $U_S$ and $U_F$, could be further reduced when there is a platform to normalise loads of DRs with those of other chemicals in wastewater. More effort is needed in the future study to refine the back estimation method so as to improve the confidence of the estimated data.

## EH01 - Ecosystem services in natural, agricultural and urban areas

**EH01A-1**

**Going beyond qualitative assessment of ecosystem services**

RA Pastorok, DV Preziosi
Integral Consulting, Inc, WOODINVILLE, United States of America

Understanding ecosystem services and their flows to human populations depends on a reliable assessment of ecological structure and function. The basis for this understanding should be an analysis of food webs and interactions among species because together they provide the mechanisms by which biological communities and associated ecosystems persist. It is necessary to develop both statistical and theoretical relationships between ecosystem structural metrics (e.g., species richness, biomass, population abundance, and habitat connectivity/fragmentation) and functional metrics (e.g., productivity, population persistence, resilience, and nitrification). Because there are few empirical data on basic relationships between ecological structure and function, ecological modelling will continue to play a central role in developing an understanding of ecosystem services in a general as well as site-specific sense. Examples of analytical tools for evaluating ecological structure and function relationships include models of: 1) single-species populations, 2) food webs (biological communities comprised of multiple species), 3) ecosystems (communities plus abiotic components of the environment), and 4) landscapes (including spatial scales encompassing multiple ecosystems). Because empirical assessments of relationships among ecological variables are limited, we maintain that attempts to assess ecosystem services in the absence of modelling populations, food webs, and/or landscapes could fail. We have no shortage of metrics to assess ecological structure, function, and services. The pressing issue, which ecological modelling can help address, is which of these metrics are most useful and cost-effective.

**EH01A-2**

**Mapping soil biodiversity and ecosystem services in the Netherlands**

M Rutgers, HJ van Wijnen, AJ Schouten, C Mulder, D de Zwart, AM Breure
National Institute for Public Health and the Environment, BILTHOVEN, The Netherlands

Soil policy in the Netherlands is in a transition phase - it is changing from a focus on the protection and restoration of soil from threats such as contamination and sealing, towards a focus on sustainable land use. A key aspect of the new focus is that soil quality should be assessed using chemical, biological and physical indicators in a systems approach. Furthermore, soil ecosystem services will be the basic concept in a framework for sustainable land use in order to split up the denominator 'soil quality' in meaningful aspects for society. We used data from the Netherlands Soil Monitoring Network (NMSN), including the Biological Indicator for Soil Quality (BISQ), to produce habitat-response relationships as proxies for soil biodiversity. These proxies were used to map soil biodiversity. Parallel to habitat-response modeling, functions for the performance of ecosystem services were produced based on biological, chemical and physical parameters. These functions will also be used for mapping purposes and their usefulness discussed. Maps were produced showing 1) predicted soil biodiversity (for several proxies of soil biodiversity), 2) predicted performance of ecosystem services (for several ecosystem services) and 3) the difference between predicted and expected performance of ecosystem services when the land use is sustainable. The expected state of a soil with a sustainable management (good ecological status) was characterized by a panel of experts. Maps were generated for both agricultural and nature areas. It is the aim of the maps to raise public awareness and to give support towards transition to sustainable land use. It is given acknowledgement that with current data, knowledge and consensus, the level of uncertainty of these maps is quite high. However, the general trends on a national scale may be helpful to show the potential for ecosystem services in The Netherlands.

**EH01A-3**

**An ecosystem services framework: a case study on citrus production and insecticide use. To what extent are specific ecosystem services affected?**

S Deacon[1], GS Reub[2], G Greene[2], SM Norman[3]
[1]ENVIRON UK, Ltd, WILTSHIRE, United Kingdom
[2]ENVIRON International, SEATTLE, United States of America
[3]Dow AgroSciences, OXFORD, United Kingdom

The findings of this pioneering proof-of-concept study will deliver a case study to inform discussions between scientists and policy makers in pesticide regulation and stakeholder discussions with the European Food Safety Authority (EFSA) where an ecosystem services approach can inform risk management decisions.

In this study, an ecosystem services framework has been developed and is applied to a key insecticide for use in citrus growing. In the southern European Union (E.U.), citrus growing is particularly important both economically and culturally to the communities in these regions and nationally. The study focusses on Southern Spain where generations of farmers have grown citrus fruits with some regional landscapes being dominated by citrus groves. Spain has long been a leading producer and foremost exporter of oranges with nearly 6.5 million tonnes produced by the European Union in 2007/08.

Recent scientific thinking is increasingly focussing on the ecosystems services approach. The concept, advanced by the Millennium Ecosystem Assessment, brings a fresh approach to managing identified ecological risks in a holistic manner. EFSA has recently developed and published a framework for deriving specific protection goals for the environmental risk assessment of pesticides. The EFSA framework is based on the ecosystem services approach.

The ecosystem services approach identifies and values the primary ecosystem services that a habitat or 'property' may provide to humans given different land uses and actions (e.g. food production; recreation; biodiversity). The type, quantity, and quality of ecosystem services provided by an area are influenced by the surrounding landscape and land uses. Human activity can affect the quality and quantity of each ecosystem service provided. Overall, some services may be improved, some services may not be affected, and some services may be harmed. A systematic evaluation of such changes in service flows is required to allow for consistent comparisons across alternatives, as well as to optimise the achievement of environmental objectives while maximising benefits and minimising costs to society.

The framework developed for this study builds on the EFSA specific protection goals and demonstrates how an ecosystem services framework is applied by identifying and valuing the primary environmental services that a habitat may provide given different land uses and actions in citrus growing regions.

**EH01A-4**

**Enhancing multiple ecosystem services in existing grass buffer strips**

RJ Blake[1], BA Woodcock[2], DB Westbury[1], P Sutton[3], SG Potts[1]
[1]Centre for Agri-Environmental Research, READING, United Kingdom
[2]NERC Centre for Ecology and Hydrology, WALLINGFORD, United Kingdom
[3]Syngenta, BRACKNELL, United Kingdom

Plant and invertebrate diversity plays a key role in terrestrial agro-ecosystems through the provision of multiple ecosystem services. Plants are the primary producers, while bumblebees pollinate crops and wildflowers, and spiders can help control crop pests such as aphids. Butterflies, particularly as larvae, and spiders also represent key food items for higher trophic levels including birds. Despite their importance, agricultural intensification has led to widespread declines in invertebrates and other taxa in the UK and NW Europe. In response to these biodiversity losses Agri-Environment Schemes (AES) were introduced and provide farmers with financial incentives in return for environmentally sensitive farming. A popular option is the establishment of perennial grass buffer strips with over 29,000 ha currently under UK AES agreements. However these strips tend to lack a wildflower component and as such are botanically species-poor. Studies have demonstrated how scarification of the buffer strip surface to create bare ground and application of graminicide to suppress competitive grasses can promote the development of sown wildflowers, benefitting invertebrates. The aim of this study was to investigate how the enhancement of existing grass buffer strips can be used to promote the abundance of bumblebees, butterflies and spiders, thereby supporting multiple ecosystem services.

The study was initiated in spring 2008 on two arable farms in Berkshire, UK on the outer 4 m of existing 6 m grass buffer strips to investigate two management practices: (a) scarification to create bare ground into which wildflower seeds were sown; (b) graminicide (fluazifop-P-butyl) application to reduce the competitive dominance of grasses.

The combination of scarification, sowing and graminicide resulted in the greatest abundance of sown wildflowers, and of bumblebees and butterflies reflecting a higher availability of foraging resource. Abundance of orb-weaving spiders responded to the sown wildflower cover, probably due to the utilisation of vegetation structures, e.g. inflorescences, to construct webs, and also higher prey densities. Incorporating these management tools into existing agri-environment options could benefit key invertebrate groups and support the delivery of multiple ecosystem services in arable landscapes.

**EH01A-5**

**A SETAC Pellston Workshop on the risks from pesticides to pollinators: feedback and basis for the future from a regulatory perspective**

T Steeger[1], F Streissl[2], A Alix[3], J Pflugfelder[4]
[1]U. S. Environmental Protection Agency, WASHINGTON DC, United States of America
[2]European Food Safety Authority, PRAPER Unit, Ecotoxicology, PARMA, Italy
[3]Ministère de l'Agriculture, DGAl-SDQPV-BRMMI, PARIS, France
[4]Swiss Bee Research Center, Agroscope Liebefeld-Posieux ALP, BERN, Switzerland

There have been reports, in recent years, of declines in native and managed pollinators in several regions of the world. Modern crop management practices to ensure a proper control of pest populations and diseases have been identified as a factor in these declines. Plant Protection Products (pesticides) are part of these management practices. Regulatory measures have been adopted requiring an assessment of the potential impact of these products on a broad range of taxa; included in the taxa evaluated are terrestrial arthropods especially those which are considered beneficial such as pollinating insects and honey bees (Apis mellifera) in particular.

Concerns which the use of pesticides in crop protection have raised for pollinators varies among countries as a function our understanding of their effect on crop pollination, the nature of the tools that are available for the risk assessment, and observed adverse effects in the field. The regulatory processes aimed at assessing the risks of pesticides to pollinators may differ from one country to another, and may not account for some key potential routes of exposure which were not identified as of concern at a local level.

A global Pellston SETAC workshop on estimating the potential risks of plant protection products to insect pollinators in January 2011 aimed to bring together the best available science regarding exposure and effects assessment methodologies for Apis and non-Apis bee species, and harmonize further the risk assessment approaches among North and South America, Europe, Australia. The workshop reviewed the state of the art science in (1) assessment of the exposure of pollinators to pesticides, (2) assessment effects using laboratory tests, (3) assessment of effects using field studies and (4) risk assessment strategies. A fifth expertise group was charged with evaluating exposure, effects and potential risks of pollinators other than the honey bee (non-Apis bee pollinators). The SETAC Pellston workshop organized around the question of pollinating species exposed to Plant Protection Products is the first experience in the area of sharing science and regulatory expertise at the world scale on a common concern with the aim to further improve the relevance of regulatory recommendations. This presentation will compare and contrast the outcome of the Pellston workshop from the perspective of regulatory agencies in North America and Europe.

**EH01A-6**

**Use of ecosystem services concept to determine need for open soils in urban areas**

J van Wensem
Soil Protection Technical Committee (TCB), THE HAGUE, The Netherlands

The draft Soil Framework Directive contains an obligation to limit the permanent covering of soil with impermeable material as far as possible and, where soil sealing is unavoidable, to mitigate the negative effects of doing so. In order to be prepared for the possible implementation of the Soil Framework Directive, the Dutch Ministry of Environment requested TCB to report on the cases in which sealing needs to be limited and how this can be achieved. As a follow-up the Ministry requested to indicate a minimum percentage of open soil in each type of development area, in order to put a limit to negative effects of sealing on soil functions. This paper addresses the establishment of a minimum percentage of open soils in urban areas. The minimum percentage of open soils in urban areas was estimated by the space needed by soils to provide or support ecosystems services to the inhabitants. The area of open soil necessary for temperature regulation and contribution to human health and well being is estimated at 5 to 10% of the urban area. Water regulation via soil needs much more space. 'The more, the better' can be concluded for biodiversity in urban areas, provided there is horizontal and vertical diversity in vegetation and good interconnectivity between areas with open soils. Surface water also contributes to certain urban ecosystem services. Based on all findings, it was concluded that 20 to 40% of the urban area should be reserved for open soil and water to provide all necessary ecosystem services. These values should be used at the scale of neighbourhoods. Not only the total area of open soil and water matters, the locations and good connections between these are crucial too.

**EH01B-1**

**Ecosystem services for life cycle assessments**

N Finisdore
World Resources Institute, WASHINGTON, United States of America

Integrating ecosystem services considerations into life cycle assessments (LCA) will improve the effectiveness of these assessments by expanding the range of environmental aspects included in assessments and providing more emphasis on the dependence companies have on ecosystem services.

Business and communities both depend and impact ecosystem services, or the benefits derived from ecosystems. For example, forests supply timber and wood, fibre, regulate climate by absorbing carbon dioxide, and yield genetic resources for medicines. Coral reefs attract tourists, serve as nurseries for commercial fish species, and protect properties along coastlines from storm surges. Wetlands absorb waste, help reduce floods, and purify water. However, most life cycle assessments do not consider the full range of ecosystem services related risks and opportunities, possibly leaving firms vulnerable to risks or unaware of opportunities related to their dependence and impact on ecosystem services.

Numerous strategies are emerging to provide life cycle assessment professionals the means to expand LCA efforts. These strategies will be reviewed for the value in different contexts and impediments to advancement will be discussed.

**EH01B-2**

**Indicator based environmental quality and quality of life in urban areas**

PD Hansen
TU Berlin, BERLIN, Germany

AbstractA comprehensive strategy is necessary to protect the ecology and characterise reference conditions in urban heavily modified areas and new towns. The importance of the quality components defined by the "good ecological status", "good chemical status"and "quality of life"will be demonstrated in this study by "on site effects monitoring"tools to promote an environmentally sensitive and sustainable use of the resources in urban areas. The study contributes to the resource management, evaluation of the interaction of ecosystems and urbanisation as well as quantification of risk. The idea behind "Contribution of Sustainability"was to summarize and assess the measures and aims for a sustainable development, while the idea behind "Field of Sustainability"was to assign these aspects to one (or multiple) of the five columns of sustainability (Economy, Ecology, Social, Cultural, Governance).

**EH01B-3**

**Sustainability indicators as decision-support tools for spatial planning**

V Castellani[1], S Sala[2]
[1]University of Milano Bicocca, MILAN, Italy
[2]European Commission - Joint Research Centre, ISPRA, Italy

To ensure sustainability of living, especially in urban areas, spatial planning should be based on reliable evaluation of benefits and cost of each alternative, taking into account also the ecosystem services provided by the natural environment, and their role in support to human living and human societies. It is therefore necessary to include in the evaluation of planning procedure (e.g. within Strategic Environmental Assessment, SEA) some decision support tools that take into account also the private consumption component and its relative effects. The present work is an attempt to perform SEA integrating the more traditional evaluation made through a set of indicators (which results are compared with local limits) with other sustainability assessment methodologies. The idea is to include in the evaluation some issues of global concern, such as resource depletion and climate change and to reinforce the use of the carrying capacity concept within the local planning. The evaluation includes Ecological Footprint (EF) assessment of citizens' consumption and a carbon balance (CB) of the area. The case study presented refers to the implementation of this approach in the Strategic Environmental Assessment of a spatial planning plan of four municipalities in Northern Italy.

The case study presented highlights the importance to support the definition of spatial planning programs with suitable tools, such as sustainability composite indicators, that are able to consider a wider range of aspects, with reference to the carrying capacity concept. The proposed methodology proved to be quite useful, even if there are some limits, such as the fact the EF method doesn't allow for accounting multifunctionality of ecosystems (e.g. carbon storage and wood provision from forests).

**EH01B-4**

**Sustainability assessment of forest biomass supply chain at local scale: carrying capacity of the system for energy valorisation**

S Martire, AG Grassini, VC Castellani, SS Sala
Università degli Studi di Milano Bicocca, MILANO, Italy

Evaluation of the trade-off between the benefits coming from forest resources' use and the conservation of forest ecosystems is needed. Considering the use of biomass for energy purpose, on one hand the use of wood resources should be based on an evaluation of the "carrying capacity"of the forest ecosystem and site-specific characteristics; on the other hand, the role of biomass valorisation has to be assessed considering the socio economic benefit or drawbacks due to the further development of the supply chain.

In the context of a site -specific sustainability assessement of a wood energy supply chain, the research focuses on development of an expeditious methodology to obtain georeferred quantity of biomass at local scale for mountain forest areas, in order to facilitate energy planning that considers the local system carrying capacity and the potential of substitution of fossil fuels.

Methodology developed for the site-specific assessment of the biomass availability, with respect to carrying capacity, consists of quantification and spatial distribution (using Geographic Information System) of forest biomass that considers local features as reported in local territorial plans and it applies Life Cycle Assessment for supporting the overall environmental assessment.

Biomass value calculated has been converted from volume to mass, considering species features and water content. The result is compared with current utilization of wood, and waste products from forestry processing are estimated, in order to quantify the mass available for energy valorisation. Then, the energy potential is estimated, from biomass quantity and from wood features, principally the lower calorific value and water content for each species. Finally, the potential of substitution of fossil fuels is calculated, knowing energy potential from available biomass for energy use.

The methodology is applied to two mountain areas, Comunità Montana Lario Intelvese (CMLI) and Comunità Montana Triangolo Lariano (CMTL), in northen Italy (Como Province).

The proposed methodology evaluates the possibility that forests can provide the supply of raw material for energy production among ecosystem services. In addition, this assessment aims to integrate considerations to protect the other ecosystem services. Moreover, the proposed methodology is useful for a preliminary assessment of the possibility to considering woody biomass in energy planning at local level.

**EH01B-5**

**Is the European honeybee (Apis mellifera mellifera) a good representative for other pollinator species?**

I Roessink[1], J van der Steen[2], M Kasina[3], M Gikungu[4], R Nocelli[5]
[1]Alterra, Wageningen UR, WAGENINGEN, The Netherlands
[2]Plant Research international, WAGENINGEN, The Netherlands
[3]Kenya Agriculture Reserach Insitute, NAIROBI, Kenya
[4]National Museums of Kenya, NAIROBI, Kenya
[5]Federal University of Sao Carlos, ARARAS, Brazil

Pollinators are important components of biodiversity and provide a key ecosystem service through pollination. Worldwide pollinator risk assessment is primarily based on European honeybee data. However, the European honeybee is not necessarily the most efficient pollinator for some high value crops (e.g., coffee) and it is not clear if a European honeybee based risk assessment is protective for other relevant pollinators.

In a first attempt to test if *Apis mellifera mellifera* is a good representative for other pollinators a first-tier contact $LD_{50}$ test using the organophosphate dimethoate was performed with several pollinator species originating from The Netherlands, Brazil, and Kenya, respectively. Thus aquired $LD_{50}$ data was used to contruct an Species Sensitivity Distribution curve ranking the different species by their response to direct contact with the toxicant.

Results from identical test set-ups with *Bombus terrestris*, *Apis mellifera mellifera*, *Apis* sp. (africanized), *Apis mellifera scuttelata*, *Scaptotrigona postica*, and *Meliponula ferruginea* show that although the European honeybee s not the most sensitive species tested the difference with the most sensitive species (*Apis mellifera scuttelata*) comprises only a factor 3. This difference does not lead to different outcomes in the risk assessment procedure. Although further testing with solitary bees and compounds with different mode-of-action is needed this first tests seem to indicate that for at least organophosphates the use of European honeybee data is protective for other pollinators.

**EH01B-6**

**Sediment Ecological Risk Assessment (SEcoRA)**

SE Apitz
SEA Environmental Decisions Ltd, LITTLE HADHAM, United Kingdom

In spite of countless papers invoking the concept, it can be argued that the term sustainable sediment management has little value, as sediments are not managed for their own sake, nor, in many cases, are they managed in a truly sustainable manner. Managing sustainability in ecosystems requires the understanding and management of all aspects, both natural and anthropogenic, of the ecological and biophysical environment in a manner that sustains ecosystem services. Sediments, or the soil/sediment continuum are essential, but just part of that system and their management does not stand alone. At best, we can provide frameworks for understanding and managing the role of sediments in sustaining ecosystem services. This paper will describe an effort to provide a language and conceptual framework in support of that goal. For the most part, soil and sediment themselves do not provide ecosystem services. Rather, soil and sediment status provides a range of functions essential to the viability and sustainability of a variety of ecosystem services. Sediment (or soil) status, defined here as a combination of the attributes quality, quantity, transport and location, is controlled by landscape and watershed biophysical conditions. These attributes are affected by natural and intrinsic conditions and by anthropogenic management of the landscape to optimize preferred ecosystem services. A range of biotic and abiotic endpoints have sediment status requirements; the extent to which sediment status meets those needs affects the role of sediment (positive or negative) in terms of that endpoint, and in terms of how sediment effects ecosystem services provided by or represented by that endpoint. ERA concepts have been adapted to identify the pathways of impact by which sediments link the ultization of ecosystem services on land affects downstream aquatic ecosystem services; these approaches will be descibed. The development of sediment ecological risk assessment (SEcoRA) approaches will allow for a better understanding of the interacting positive and negative roles of sediment in the maintenance of ecosystems and the socioeconomic functioning of rivers, considering various dynamic aspects of the interactions between sediment status and various endpoints in a spatially explicit manner.

## EH02 - Monitoring and modeling stressed ecosystems to support ecosystem-based management

**EH02-1**

**Modelling the impact of endocrine disruptions on aquatic ecosystems: an experimental lake study**

L Clouzot[1], C Metcalfe[2], KA Kidd[3], PA Vanrolleghem[4]
[1]ModelEAU, université Laval, QUEBEC, Canada
[2]Trent university, PETEROBOROUGH, Canada
[3]Canadian Rivers Institute, University of New Brunswick, SAINT JOHN, Canada
[4]ModelEAU, Université Laval, QUEBEC, Canada

Despite growing concern towards endocrine disrupting chemicals (EDCs), impact on wild populations and their consequences on ecosystem services remain unknown. Single-species tests are prefered over experiments in enclosed ecosystems for the experimental ease of work and the higher reproducibility. Ecosystem modelling is not used as a general tool because of the need for extensive calibration for a specific ecosystem. However, the goal of environmental risk assessment and ecosystem-based management is to maintain ecosystem functions and services. Thus, ecosystem modelling is the logical next step in predicting impact of chemicals on aquatic and terrestrial ecosystems. This study aims to develop a simplified ecosystem model that can be used as a tool to predict EDC impacts on aquatic ecosystems. The model development is more focused on predicting ecological effects of EDCs rather than their impact on population dynamics. An object oriented framework for ecosystem modelling was developed in the software package WEST with equations based on the AQUATOX model (USEPA, 2002). Reproductive endpoints had to be added in the model to incorporate the endocrine disruptions that are commonly measured. The model consists of (i) a food web model (ii) toxic effect sub-models and (iii) a model for nutrient and detritus cycling. Field data are used to help in developping and validating the model. A multi-year whole-ecosystem study is performed at an experimental lake with exposure of well-defined fish and lower-trophic-level populations to environmentally-relevant concentrations of the synthetic hormone 17α-ethinylestradiol (EE2). The experimental lake is located in an undisturbed watershed and contains naturally reproducing populations of fish, benthic invertebrates, zooplankton and algae. The study started in 1999 with baseline data collected until 2000 on aquatic populations in the experimental lake and references lakes. Between 2001 and 2003, EE2 was added continously in the experimental lake. Since 2004, EE2 addition was stopped to measure ecosystem stability and recovery after stressor removal. In contrast with the reference lake, the Fathead minnow population in the experimental lake collapsed after the second year of EE2 addition. This reproductive failure was maintained after the EE2 addition was stopped, although few small individuals indicate some reproduction was occuring.

### EH02-2

**Response of red fox populations to rodent field controls with bromadiolone: a 6 year study on regional scale**

M Jacquot[1], M Coeurdassier[1], G Couval[2], R Renaude[3], D Truchetet[4], F Raoul[1], P Giraudoux[1]
[1]Chrono-environnement, UMR UFC/CNRS 6249 USC INRA, Université de Franche-Comté, BESANCON, France
[2]FREDON Franche-Comté, BESANCON, France
[3]Fédération Départementale Des Chasseurs Du Doubs, GONSANS, France
[4]DRAAF/SRAL de Franche-Comté, BESANCON, France

Anticoagulants rodenticides are mostly used to control rodent populations and may cause severe secondary poisoning of rodent predators. In 90's, hundreds of predators (mainly common buzzard, red fox, and red kite) died after large-scale treatments with bromadiolone bait (60,000 ha) in the Doubs department (France). This poisoning led to changes in the legislation and treatment practices.The present study aims at checking whether Arvicola terrestris controls with bromadiolone have a long term depleting effect on fox populations and whether the evolution of treatment practices decrease undesirable side effects on fox populations.
Treatment intensity was quantified as the quantity of baits used each year on each commune. Red fox populations were monitored by night spotlight counts performed along 472 transects of 1-2 km. Fox counts were carried out in spring and small mammal controls in autumn. Therefore, fox densities obtained per commune for a year n (2004 to 2009) were related to treatments the year n-1 (2003 to 2008). Treatments of the year n-2 were used to investigate possible delays. For each transect a Kilometric Abundance Index (KAI) was calculated and values were interpolated on the centroid of each commune by ordinary kriging.
The model with the lowest AICc selected to explain kriged fox densities a year n includes bromadiolone treatments of the years n-1 and n-2. Intensive treatments led to KAI decrease. Impact was important in 2004, fox counts being lower in the areas where treatments were carried out in 2003. Visual examinations of maps show that KAI generally stayed extremely low in large areas until 2005 and partially recovered the following years. The same areas were treated again from 2006 to 2008 during the next vole outbreak and bait quantities per hectare were decreased by 2 at the minimum. Those treatments were not followed by a decrease of fox KAI.
The present work is the first one to address the issue of the impact of bromadiolone treatments on natural foxes populations on a very large scale (about 5,000 km2) and permitted to evaluate the resilience of populations to treatment. This approach shows an additionnal example of how monitoring wildlife population on the long term using index method may provide valuable informations about adverse effects of pesticide treatment. It also shows that treatments carried out at low density of vole population are likely to have a lesser impact on fox populations.

### EH02-3

**PCB-induced changes of a benthic community and expected ecosystem recovery following in-situ remediation**

ML Janssen[1], K Thompson[2], N Luoma[2], G Luthy[1]
[1]Stanford University, STANFORD, United States of America
[2]United States Geological Survey, MENLO PARK, United States of America

The benthic community was analyzed to evaluate pollution-induced changes for the polychlorinated biphenyl (PCB)-contaminated site at Hunters Point (HP, California) and 30 reference sites in the San Francisco Bay. An analysis based on functional traits of feeding, reproduction, and position in the sediment shows that HP is deprived of deposit feeders, subsurface carnivores, egg laying species, and species with no/weak protective barrier. Sediment chemistry analysis shows that PCBs are the major risk drivers at HP (1570 ppb) and that the reference sites contain much lower levels of PCB contamination (9 ppb). Different feeding traits present a direct pathway of exposure, which can be mechanistically linked to PCB bioaccumulation by biodynamic modeling. The deposit feeder Neanthes arenaceodentata accumulates about 20-times more PCBs in its lipids than the facultative deposit feeder Macoma balthica and up to 180-times more than the filter feeder Mytilus edulis accumulates though the aqueous phase. In situ sorbent amendment can reduce the PCB bioavailability from sediment but long term monitoring data of full-scale field amendments are not existing to date. To overcome the lack of data, the modeling framework was used to evaluate the remedial success regarding ecosystem recovery. The comparison of different exposure scenarios suggests that PCB tissue concentrations at HP are two orders of magnitude higher than at the reference sites. The model further predicts that a full-scale sediment amendment with activated carbon can reduce PCB bioaccumulation at HP by up to 85 to 90% under favorable field and treatment conditions. The modeling demonstrates that such remedial success corresponds to exposure conditions suggested by the sediment quality guidelines and the cleanup goal for HP but concentrations remain slightly higher than at the reference sites. The present study demonstrates how the remedial success of an untested sorbent amendment, which lowers the PCB availability, can be compared to reference conditions and traditional cleanup goals, which are commonly based on total sediment concentrations.

### EH02-4

**Recovery potential of diatomic biofilms after industrial contamination (Cd, Zn) : field and experimental studies**

A Arini[1], A Feurtet-Mazel[2], M Coste[3], F Delmas[3]
[1]University Bordeaux 1, ARCACHON, France
[2]Universirty Bordeaux 1, ARCACHON, France
[3]CEMAGREF, CESTAS, France

This study was conducted in a context of metal impacted hydrosystem remediation (Cadmium and Zinc) on periphytic diatoms biofilms, dominant primary producers in freshwaters. It aims to combine in situ and laboratory studies to assess first biological modifications on biofilms in decontamination conditions in order to understand the remediation procedure effects.
The colonization of biofilms was conducted during 24 days on a site undergoing industrial discharges and on a metal-free site considered as control. After 24 days, a first batch of contaminated biofilms was translocated to the metal-free site to undergo natural decontamination, and a second was brought to laboratory into artificial streams containing metal-free medium, to carry out decontamination experiments under controlled conditions. Biofilms from the metal-free site were also brought in the laboratory as control biofilms.
Different tests were then performed: analyses of metal bioaccumulation, taxonomic investigations, biovolumes and teratological forms measurements, diatom densities numerations, completed by physicochemical measurements in water.
Contaminated biofilms translocated to the metal-free site showed a very fast metallic decontamination potential and after only 24 days most of species were similar to those found into control biofilms : only a few species, like Eolimna minima, considered as metal-resistant, were still found into biofilms, but in very low densities.
Otherwise, metal concentrations into biofilms under laboratory decontamination showed a sharp decrease but both Cd and Zn stay significatively higher than concentrations analyzed into control biofilms after 56 days of decontamination. Moreover, taxonomic inventories do not highlight a complete recovery of diatom communities : metal-resistant species persist with high abundances after 56 days of decontamination.
By comparing results from field and laboratory experiments, it appears that decontamination under natural conditions was faster. This assemblage recovery suggests the involvement of species immigration and emigration from the natural environment which prevail over multiplication rates of pre-established species.
Complementary experiments would be necessary to assess the real importance of diatom import or export into biofilm and their effects on the evolution and then recovery potential of diatom community structures.

### EH02-5

**Establishing environmental risk based management for industrial operations in (sub-) Arctic marine areas. Linking early warning signs to whole organism effects from individual to population levels.**

T Baussant[1], H Jonsson[2], A Ingvarsdóttir[2], RK Bechmann[2], IC Taban[2], A Skadheim[2], DM Pampanin[2], S Bamber[2], E Ravagnan[2], DØ Hjermann[3], OJ Christie[4], L Pinturier[5], L Bracco[6], M Buffagni[7], S Sanni[2]
[1]International Research Institute of Stavanger (IRIS), RANDABERG, Norway
[2]IRIS, RANDABERG, Norway
[3]Univ. Oslo (CEES), OSLO, Norway
[4]InfoStrat, SANDNES, Norway
[5]Total E&P Norge AS, STAVANGER, Norway
[6]Eni Norge AS, SANDNES, Norway
[7]Eni E&P division, MILANO, Italy

Population and community responses to multiple stressors can be assessed by combining fate and effect modelling with information from whole organisms and individual internal processes followed by further assessment by population dynamic modelling on the population and community levels. This presentation gives an example of a foundation for such an approach based on a combination of experimental studies, monitoring and model tools.
Two subsequent projects (BioSea I&II; 2001-10) were focused on establishment of environmental monitoring-, risk-, and model tools for oil based discharges to the marine environment to aid environmental management. Crude oil consists of a large number of chemical constituents representing a combination of different stressors.
An objective of the BioSea II project (2007-10) was to adopt the tools to (sub-) Arctic areas. This was fulfilled through a series of experiments with ecologically relevant (sub-) Arctic fish and invertebrate species (Atlantic cod, halibut/long rough dab, Icelandic scallop and northern shrimp) at different development stages (eggs, larvae, juvenile and adults).
The following achievements were made:
_ Critical harmful effect concentrations of dispersed oil were determined based on organism survival and growth (fitness) of vulnerable early life stages.
_ Two suites of biomarkers for fish and invertebrates were evaluated for detection of responses to oil based exposures. These have been further developed into operative monitoring tools by establishing field background and threshold levels.
_ Field background levels of biomarkers were determined in species inhabiting (sub-) Arctic areas.
_ Biomarker threshold values were determined for juvenile and adults at concentrations where detrimental effects were observed in fitness of individual organisms at early, vulnerable life stages.
_ A model approach was developed to assess adverse effects on population level for one of the test species (northern shrimp).
_ Reactions of the studied species to different test conditions were studied by multivariate analyses to assess similarities/dissimilarities.
_ The use of biomarkers to monitor hydrocarbon discharges from oil and gas activities as 'Environmental Indicators' within an ecosystem based environmental management approach for the Barents Sea region was considered.

### EH02-6

**Organic pollutants, bacteria, primary producers and global change. Are we tracking the problem adequately?**

J Dachs[1], N Berrojalbiz[1], C Galbán[1], P Echeveste[2], S Agustí[2], C Encinar[1], J Zúñiga[1], A Cabrerizo[1]
[1]IDAEA-CSIC, BARCELONA, Spain
[2]IMEDEA-CSIC, ESPORLES, Spain

The total number of synthetic organic chemicals introduced to the environment by Humans has never been quantified, but it is not lower than thousands. A fraction of these chemicals have toxic effects to coastal organisms and presumably affect ecosystems structure and function. During the last decades, some of the processes affecting the transport, degradation and fate of a limited number of chemicals have been studied, and the rising concern for environmental risk of organic chemical has lead to the regulation of a few of them by national and international organisms. However, the environmental inventory of organic pollutants is far from being quantified, and current methodologies used in most toxicological tests only allow to determine effects of individual chemicals to organisms. There are major limitations on appropriate methodologies to assess the effects of organic pollutants at population and ecosystem levels and the effects induced by complex mixtures of organic pollutants present in natural environments. The modification of the composition of the biosphere by a myriad of organic pollutants at ultra-trace levels is not yet regarded as another vector of environmental change which is irreversible due to the persistent

character of many of these chemicals and due to its global coverage. Here, we claim that the modification of the atmosphere, water, sediments and biota composition is a factor to be taken into account in ecosystems, and that its pressure on the environment has been exponentially increasing during the last 6 decades of the anthropocene.
In addition, we will point out to the interactions between ecosystem functioning, trophic status, fate and transport of pollutants and carbon cycle during the anthropocene

## EP01 - Alternative flame retardants: Environmental exposure, fate and trends

### EP01-1

**Determination of organophosphorous flame retardants (OPFRs) in various matrices - including first result of OPFRs in the food chain of the Western Scheldt**

SH Brandsma, J de Boer, PEG Leonards
Institute for Environmental Studies (IVM), AMSTERDAM, The Netherlands

Halogenated flame retardants like polybrominated diphenyl ethers (PBDEs) are used in high volumes in different kind of products to enhance fire safety. Due their persistency, bioaccumulative properties and toxicity the US have started to phase-out the production of the Penta- and Octa-BDE commercial mixtures voluntary in 2004. In 2009 also the production and application of Deca-BDE commercial product has been limited. The phase-out of both products has led to an increase in the use of alternative flame retardants. Organophosphorous flame retardants (OPFRs) is one of the flame retardant groups that show an increasing production over recent years. OPFRs are also used as plasticizers and anti-foaming agents in many products such as furniture, textiles, cables, building materials, insulation materials, paints, floor polishes, hydraulic fluids and electronic appliances. In most applications OPFRs are used as additive chemical and thus not covalently bound to the polymeric materials. The objectives of the present study were to develop an analytical method to analyze OPFRs in various matrices, and to study the OPFRs in a pelagic and benthic food web in the Western Scheldt, The Netherlands. An analytical method was developed for the analysis of OPFRs in sediment and biota using LC-MS/MS. Samples of a pelagic and benthic food web from the Western Scheldt were analysed for OPFRs. The first results show that OPFRs were found in Western Scheldt suspended particulate matter (SPM) and biota. In SPM TPP, TCP and EHDP were detected, and TPP and EHDP were only detected in the benthic organism's cockle and sole. Low concentrations of TCP were also found in sole. However, higher in the pelagic food web, in herring and common tern egg concentrations of these OPFRS were below the LOD. The OPFR concentrations in sole are in the same range as BDE47, BDE99, BDE209 and α-HBCD. In conclusion, the first results show that TPP, EHDP and TCP may accumulate in the benthic food web but not in the pelagic food web.

### EP01-2

**Fate of organophosphorus flame retardants - Determination of their metabolites in human urine**

T Reemtsma, J Lingott, S Roegler
Technical University of Berlin, BERLIN, Germany

Trialkylphosphates (TAP) are a group of flame retardants that is used increasingly, also as substitute for brominated flame retardants. Besides that TAP are used as pesticides, plasticizers and as additive in many products. Owing to their widespread use TAP are also widely distributed in the environment [1]. Due to the presence in consumer products humans are exposed to TAP, and TAP have been found in biomonitoring studies, in human breast milk as well as in urine. Depending on their alcohol moiety TAP are more or less stable and hydrolysis may occur. These hydrolysis products, dialkyl phosphates (DAP) and monoalkyl phosphates (MAP), are far less toroughly investigated [2]. We have recently developed a method for the detection 14 metabolites of TAP (DAP and MAP) in human urine. This method is based on liquid-chromatography-mass spectrometry (LC-MS/MS) using ion-pair chromatography [2]. Several analytes first had to be synthesized to allow their quantitation. The method was exemplarily applied to 19 samples of different individuals [3]
In this study five MAP and two DAP were detected for the first time in human urine. Monobutyl, diethyl, diphenyl and diethylhexyl phosphate were determined with median concentrations in the µg/L-range. These first results generated with the new LC-MS/MS method suggest that the body burden for organophosphorus compounds may be much higher than visible from the sole analysis of the TAP. The inclusion of TAP metabolites in future biomonitoring studies should provide a more comprehensive picture of the exposure of humans to organophosphorus compounds.
It needs to be clarified whether the DAP and MAP determined in human urine had been formed from TAP in the human body after uptake or were transformed before uptake and incorporated as DAP and MAP, already. For that purpose also the environmental fate of TAP needs further investigation. This will also help to assess which route of exposure is most relevant for humans.

**Bioaccumulation of selected halogenated organic flame retardants in remote lakes and in the Great Lakes**

CG Muir, C Teixeira, J Epp, BH Lee, T Peart, T Young, X Wang, M Keir, S Backus
Environment Canada, BURLINGTON, Canada

In this study the bioaccumulation and concentrations in surface waters of a wide range of non-legacy halogenated organic compounds (HOCs) including replacement halogenated and non-halogenated organophosphate flame retardants (OPFRs) was determined in remote lakes within the Canadian shield and in the open Great Lakes. Large volume samples of surface waters (100 L) were collected from two remote lakes Lake Opeongo (Algonquin Provincial Park, ON) and Siskiwit Lake (Isle Royale National Park, MI) as well as from surface waters of the lower Great Lakes over the period 2005-2010. Zooplankton (>100 um), mysids, forage fish and lake trout were obtained from Lakes Erie, Ontario and Opeongo while only lake trout were available from Siskiwit Lake. Extracts were screened for 27 individual BDEs (Br3-Br10) and 20 Br3-Br6 compounds/ PBDE replacements and other HOCs using GC-electron capture negative ion mass spectrometry (GC-EC NIMS) with a HP-5MS and RTX-1614 capillary columns. OPRFs were analysed by GC-EIMS using an HP-5MS column. Br3-Br6 compounds and Dechlorane Plus (DP) were non-detect (<0.1 pg/L) in Siskiwit and near detection limits in Opeongo lake waters. Pentabromo-ethylbenzene (PBEB), 1,3,5-tribromo-2-methoxy-4-methylbenzene (Br3MeBz), allyl 2,4,6-tribromophenyl ether (ATE) and dibromopropyl 2,4,6-tribromophenyl ether (DPTE) were the most prominent non-PBDE HOCs in Opeongo lake waters; present at sub-pg/L concentrations. A larger suite of HOCs were detectable in Lake Ontario waters including DP, Br3MeBz, PBEB, DPTE, 12345-pentabromobenzene (Br5Bz), penta- and hexabromotoluene, and 2-ethyl-1-hexyl 2,3,4,5-tetrabromobenzoate (EHTeBB) although concentrations were near or at MDLs. The tris-chloroalkyl phosphates (TCEP, TCPP, TDCP) were present at 5-50 ng/L in central Lake Ontario waters. A wide range of Br3-Br6 compounds were detected in zooplankton from Lake Ontario including Br3MeBz, 1,3,5-tribromobenzene (TBB), tetrabromoxylene (TBX), bis(tribromophenoxy)ethane (BTBPE), PBEB, and BPTE. Lake Opeongo zooplankton had a more limited suite, with Br3MeBz, ATE and Br5Bz present at low pg/g (wet wt) concentrations. BDE47, BDE153 and Br3MeBz had the highest trophic magnification factors based on the slope of the log (lipid wt) concentrations versus trophic level. TBX, 1,3,5-TBB and BTBPE showed trophic dilution while other compounds e.g. BDE202 (and other hepta- and octaBDEs) were detectable in most samples but showed limited increases with trophic level.

### EP01-4

**Brominated flame retardants and Dechlorane Plus in air and seawater from the German Bight, North Sea**

A Möller, Z Xie, R Sturm, R Ebinghaus
Helmholtz-Zentrum Geesthacht, Centre for Materials and Coastal Research, GEESTHACHT, Germany

Brominated flame retardants (BFRs) have been used for more than 50 years to reduce the flammability of various industrial and commercial products. Polybrominated diphenyl ethers (PBDEs), which are currently the most well studied BFRs, are known to be toxic, bioaccumulative, persistent, are ubiquitous in the environment and undergo atmospheric transport over long-ranges. As a result of the banishment of the industrial Penta-, Octa-, and DecaBDE mixtures, the industry shifts towards alternative, unregulated brominated (BFRs) and non-brominated flame retardants. Even though some alternative BFRs such as 1,2-bis(2,4,6-tribromophenoxy)ethane (BTBPE) and, only recently, the chlorinated flame retardant Dechlorane Plus (DP) have been detected in the environment, their environmental fate and transport behavior, especially in the marine environment, is not well understood. Therefore, we investigated the occurrence and air-sea exchange of PBDEs, non-PBDE BFRs and DP in the German North Sea. Paired air and water samples were taken aboard the German research vessel Heincke during three cruises in 2010. The samples were Soxhlet extracted and analyzed by a GC-ECNI-MS system.
PBDEs were detected in concentrations from 1 to 15 pg $m^{-3}$ and from <1 to 10 pg $L^{-1}$ in air and seawater, respectively, while the congener profile was dominated by BDE-47, -99, -100 and BDE-209. Among the non-PBDE BFRs, 2,3-dibromopropyl-2,4,6-tribromophenyl ether (DPTE) and hexabromobenzene (HBB) were detected in concentrations similar to the PentaBDE congeners and DP showed similar concentrations and spatial trends as BDE-209. This suggests that DP is used as replacement for BDE-209. The highest atmospheric concentrations resulted from land air masses passing Germany and the Netherlands while lower concentrations were observed for oceanic and Scandinavian air masses. The air-seawater exchange was dominated by deposition into the North Sea showing that atmospheric transport is an important source of flame retardants in the North Sea besides dry and wet deposition and riverine discharges from highly industrialized rivers such as the Rivers Elbe and Scheldt.

### EP01-5

**Emerging flame retardants in the atmosphere of the Great Lakes**

M Venier, Y Ma, A Salamova, RA Hites
Indiana University, BLOOMINGTON, INDIANA, United States of America

Flame retardants are a large group of chemicals, of which polybrominated diphenyl ethers (PBDEs) represent the vast majority. Flame retardants are added to numerous products to prevent fire, and their usage has increased rapidly since about 1980s, probably as a result of stringent fire safety regulations. In 2004, two commercial PBDEs mixtures were voluntarily retired from the United States market (Penta-BDE and Octa-BDE); the other widely used commercial mixture, Deca-BDE, is still largely unregulated in the United States and Canada, although it was recently banned in the European Union. As a result of their heavy usage, PBDEs are ubiquitous in the environment, having been detected in air, sediments, biota, and people. In addition, the market has been continuously replacing banned or retired products with unregulated compounds. Air samples (vapor and particles) were collected within the Integrated Atmospheric Deposition Network (IADN) at five sites around the Great Lakes. In this study, we focused on "emerging"brominated flame retardants including i.e. α-, β-, γ-, and δ-tetrabromo-ethylcyclohexane (α-, β-, γ-, and δ-TBECH), allyl-2,4,6-tribromophenyl ether (ATE), 2,3-dibromopropyl-2,4,6-tribromophenyl ether (DPTE), 2-bromoallyl-2,4,6-tribromophenyl ether (BATE), octabromotrimethylphenyl-indane (OBIND), hexachlorocyclopentenyldibromocyclooctane (HCDBCO), bis(2-ethyl-1-hexyl) tetrabromophthalate (TBPH), and 2-ethyl-1-hexyl-2,3,4,5-tetrabromobenzoate (TBB). With the exception of OBIND, all of the compounds listed above were detected in air samples, although for some of them, the frequency of detection was low. Interestingly, TBPH and TBB have not been found in biota, indicating that they may be readily metabolized, but their presence in air suggests that they are subject to long range transport. These two "emerging"flame retardants were found most frequently and at highest levels at the urban sites (Chicago and Cleveland), with some detection at a rural site (Sturgeon Point). Their concentrations were generally higher in the particulate phase as compared to the vapor phase. The levels of TBPH and TBB in the filters were on the order of 5 pg/$m^3$, which is comparable to those of BDE-47. The majority of the other compounds were found in the vapor phase and at all the sites, from rural to urban with levels around 1 pg/$m^3$, which are similar to the levels of BDE-47 at the rural sites.

### EP01-6

**Flame retardants hexabromobenzene, pentabromotoluene and pentabromoethylbenzene: their presence and Norway and environmental partitioning properties**

HPH Arp[1], T Møskeland[2], PL Andersson[3], J Rattfelt Nyholm[3]
[1]Norwegian Geotechnical Institute (NGI), OSLO, Norway
[2]Det Norske Veritas (DNV), HØVIK, Norway
[3]Umeå University, UMEÅ, Sweden

The brominated flame retardants (BFRs) pentabromotoluene (PBT), pentabromoethylbenzene (PBEB) and hexabromobenzene (HBB) have been in use for several decades. HBB is used for fireproofing plastics, textiles and wood, and can be released from BFR polymers. PBT and PBEB are found in unsaturated polyesters and are used for textiles and adhesives. These BFRs have physical chemical properties similar to other persistent organic pollutants (POPs), and have been identified as potential arctic contaminants in screening studies. Studies on these BFRs can be found from the 1980s, especially in Japan regarding HBB. However, not much research was done during the 1990s and only recently are these three compounds being reported again in environmental samples. The reason for this disappearance and reappearance in the environmental literature is unclear, and could reflect changing production levels or simply changing concern for these compounds. To investigate the presence of HBB, PBT and PBEB, we conducted a screening study of these samples in multi-media environmental samples (diverse biota, air particles, waste water treatment plant samples, etc.) in three areas of Norway that are suspected source zones for BFRs: Drammen, Lillehammer and Tromsø. Additionally, we used various approaches to estimate their partitioning properties and environmental behavior.

## EP02 - Antimicrobial resistance in the environment

**EP02-1**

**Exploring the metagenomes of environmental antibiotic hotspots to identify resistance factors that we may face in the clinic tomorrow**

DGJ Larsson[1], A Janzon[1], A Johnning[1], NP Marathe[2], F Boulund[1], C Rutgersson[1], YS Shouche[2], ER Moore[1], E Kristiansson[1]
[1]University of Gothenburg, GOTEBORG, Sweden
[2]Pune University, PUNE, India

There is accumulating evidence that extensive resistance is promoted within environments contaminated with high levels of antibiotics. Such "hotspots"are unique in the sense that they contain diverse collections of bacteria living under unprecedented long-term antibiotic selection pressures. Thus, there is a possibility that these environments harbour yet undescribed resistance genes, resistance plasmids and chromosomal mutations that we may face in pathogens in the clinic tomorrow. Here, three parallel approaches were taken to identify novel potential resistance factors in DNA isolated from Indian river sediments contaminated with antibiotics from drug manufacturing. First, massively parallel metagenomic sequencing revealed 37 known resistance genes in the sediment, including high levels of several mobile QNR genes that are known to cause moderate resistance to quinolones. A novel resistance plasmid harboring qnrD was assembled from the sequence data and confirmed by PCR. A repeat amino-acid motif, conserved among known QNR proteins, was generated and used to identify other potential QNR genes in the metagenomes. The functionality of these tentative quinolone resistance genes remains to be tested. Second, selected regions of the genes encoding type II topoisomerases, the specific targets for quinolones, were amplified by PCR and sequenced by 454 technology to explore the presence of novel, potential resistance-carrying mutations. As a third approach, river sediment DNA was fragmented, inserted in an expression plasmid and transformed into E. coli to construct metagenomic libraries. As a positive control, we screened the libraries for acquired resistance to sulfamethoxazole, as sul2 was the most common resistance gene found by the metagenomic sequencing. Several thousand colonies of E. coli transformants were able to grow on sulfamethoxazole plates, whereas the control host strain, transfected with a plasmid without insert, was sensitive. Similar results were obtained when screening for acquired fluroquinolone resistance. These result shows that such an assay, indeed, can be used to identify resistance-conferring DNA sequences. We are currently screening the libraries for inserts providing resistance to a variety of antibiotics. Growing clones are isolated and selected inserts will be amplified by PCR and sequenced.

**EP02-2**

**Sources, pathways and mitigation of antibiotic resistance genes at the watershed scale**

A Pruden[1], M Arabi[2], HN Storteboom[2], Y Ma[1], CW Mckinney[1]
[1]Virginia Tech, BLACKSBURG, VA, United States of America
[2]Colorado State University, FORT COLLINS, CO, United States of America

This presentation will provide a framework for understanding the behavior of anthropogenic sources of antibiotic resistance in the environment as well as insight into potential strategies for reducing the risk associated with antibiotic resistance gene (ARG) "pollution". The first objective was to identify key sources and processes contributing to elevated ARGs in river environment, which was accomplished through the development and application of a novel ARG molecular signatures approach. The molecular signatures approach was demonstrated on the Cache La Poudre River, indicating that this particular river system was primarily influenced by wastewater treatment plant (WWTP) sources of ARGs. This suggests that appropriate treatment of WWTP waste streams may help reduce levels of ARGs in the aquatic receiving environment. Thus, the second objective was to explore WWTP sludge digestion and UV disinfection as potential mitigation options to reduce the spread of ARGs. Thermal hydrolysis of sludge followed by sequential anaerobic and aerobic digestion steps yielded varied responses for tetracycline and sulfonamide ARGs. It was noted that while thermal hydrolysis resulted in physical destruction of ARGs, the concentrations increased by up to an order of magnitude in the anaerobic digestion step. The subsequent aerobic digestion step resulted in further increase of sulfonamide ARGs, by almost two orders of magnitude in the case of sulI. However, tetracycline ARGs, tetO and tetW, decreased in response to aerobic digestion. In the disinfection studies, a typical inactivation curve was obtained for methicillin resistant Staphylococcus aureus in response to UV exposure, but corresponding mecA ARGs remained largely intact. The results indicate that while WWTPs are a promising node for controlling the spread of anthropogenic sources of antibiotic resistance, ARG attenuation at the WWTP is not likely to be achieved via standard practices and may require more aggressive treatments.

**EP02-3**

**Antibiotic resistance downstream of abandoned mine sites: where organisms and genes tell different stories**

W Graham[1], H Nura[1], A Jarvis[1], CW Knapp[2]
[1]Newcastle University, NEWCASTLE UPON TYNE, United Kingdom
[2]Univdersity of Strathclyde, GLASGOW, United Kingdom

Rapid and increasing development of antibiotic resistant bacteria (AR) is eroding the huge benefits of antibiotics in the treatment of disease. Although this problem partially results from inappropriate antibiotic use in medicine and agriculture, there is growing evidence that untreated wastes that contain organic and heavy metal pollutants also play a role in environmental AR development. One pollution setting where elevated AR might be apparent due to pollution is downstream of historic abandoned zinc (Zn) and lead (Pb) mines. This study compared AR using both culturing and genetic methods to quantify AR at various locations in the River Tyne watershed in Northern England, which is an ideal for assessing the effects of metal pollution on AR because one arm of the river was heavily impacted by mining, whereas the other arm is relatively pristine. Sediment Zn levels in the South Tyne ranged from ~ 4000 to 12500 mg-Zn/Kg sediment, whereas levels in the North Tyne were < 300 mg-Zn/Kg sediment. Further, culturing methods found ~ 70% of the isolated colonies were ampicillin resistant in the South Tyne and only ~ 1.0% were resistant in North Tyne. However, despite this broad difference in resistant cultured species, antibiotic gene data suggested no significant relative difference in resistance gene levels. These data show that studies that solely rely on resistance genes for detecting apparent resistance can provide misleading results, and we suggest that all future studies on environmental antibiotic resistance use culturing methods to detect resistant strains not covered by known resistance genetic markers.

**EP02-4**

**Effects of veterinary medicines introduced via manure into soil on transferable antibiotic resistance in soil bacterial communities**

K Smalla, H Heuer, CT Binh, C Kopmann, U Zimmerling
Julius Kühn Institute, BRAUNSCHWEIG, Germany

Due to the use of veterinary antibiotics in animal husbandry, considerable amounts of antibiotics are introduced into soil with manure. Antibiotics entering the environments are assumed to affect abundance of antibiotic resistance genes and their transferability. The approach of capturing transferable plasmids (conjugative or mobilizable) into a selectable recipient strain was used to study transferable antibiotic resistances in manure and manure treated soils. This cultivation-independent method allows to gain insights into plasmid diversity that might play an important role in the dissemination of antibiotic resistance genes in soils. In this study transferable plasmids conferring sulfadiazine (SDZ) resistance were directly captured in *E. coli* from manures and manure treated soils. Transfer frequencies of capturing SDZ resistance plasmids into *E. coli* were determined in soil microcosm, mesocosm and field experiments with soil treated with manured containing SDZ or not. Higher transfer frequencies were observed for soils treated with SDZ containing manure. A total of 204 captured plasmids were analysed. The majority of plasmids captured belonged to the recently discovered group of LowG+C plasmids and 15% to the IncP-1e subgroup. Restriction profiles and the plasmid encoded resistances showed that a high diversity of antibiotic resistance plasmids was captured from soil and rhizosphere samples. Although potential transconjugants were only selected based on the captured SDZ resistance, the plasmids obtained typically conferred multiple antibiotic resistances. Sequencing of these plasmids allowed further insights into the type of antibiotic resistance genes and mobile genetic elements carried on similar plasmid backbones.
Our study showed that spreading manure on agricultural soils promotes spreading of transferable antibiotic resistances and residual veterinary medicines in agricultural soils. Our data indicate that LowG+C and IncP1-_e plasmids play an important role in the dissemination of multiple antibiotic resistance in agroecosystems.

This study was funded by the Deutsche Forschungsgemeinschaft, research group FOR566 "Veterinary Medicines in Soils: Fate and Effects".

**EP02-5**

**Does fertilization with sewage sludge promote antibiotic resistance in bacteria isolated from food crops?**

E Topp[1], A Scott[1], L Sabourin[1], P Duenk[2]
[1]Agriculture and Agri-Food Canada, LONDON, Canada
[2]University of Western Ontario, LONDON, Canada

The recycling of municipal sewage sludge (biosolids) onto agricultural land as a valued source of crop nutrients is a common farming practice. Sewage sludge can contain significant concentrations of several antibiotics and broad spectrum antimicrobial agents, as well as an abundance of bacteria resistant to a variety of antibiotics of human clinical significance. In the present study a field experiment evaluated the impact of sewage sludge use according to normal farming practice on the abundance and the characteristics of viable antibiotic-resistant bacteria detected on tomatoes, potatoes, carrots and sweet corn (maize) at harvest. Municipal sewage sludge was applied at a commercial rate in May 2009 to a 72 m2 plot, with an untreated adjacent plot as a control, both of which were then cropped to barley (Hordeum vulgare). The following spring, in May 2010, both the treated and the control plots were planted with the four vegetable crops in a randomized block design. In late August 2010 the crops were harvested, bacteria washed off the surface of the vegetables, and the abundance of bacteria resistant to each of 27 antibiotics established by viable count on IsoSensitest agar medium containing each antibiotic at the clinical breakpoint concentration. There was no significant effect of sewage sludge utilization on the abundance of bacteria resistant to any antibiotic. Augmentin-, cefoxatime-, and cefoxitin-resistant bacteria were isolated and purified from carrots, tomatoes and sweet corn, foods that can be eaten raw. These were screened for resistance to the full panel of antibiotics to establish patterns of multiple antibiotic resistance (MAR). Preliminary analysis of the results suggests that the abundance of bacteria resistant to multiple (eg. >10) antibiotics is higher on the vegetables that were grown in soil fertilized with sewage sludge than in control soil. Overall, If these results are confirmed they would indicate that further investigation of a relationship between sewage sludge use in agriculture and the abundance of MAR bacteria in human food crops is warranted.

**EP02-6**

**Assessing the environmental hazard of antibiotic resistance. Considerations from a regulatory view.**

J Schönfeld, A Küster, B Rechenberg
Federal Environment Agency, Germany, DESSAU-ROßLAU, Germany

The development of antibiotic resistances in microorganisms has been identified as a major global public health problem (WHO 2001 [1], UNEP 2005 [2]). The importance of the topic has been addressed in the current guidance for the authorization of veterinary (CVMP/VICH/644/2001 [3]) and human pharmaceuticals (CPMP/EWP/520/96) [4]. In contrast, the potential adverse impact of the development and spreading of antibiotic resistances on the environment is not reflected in the current guidance for the environmental risk assessment for human as well as veterinary pharmaceuticals. Consequently, the aim of this study was to screen and evaluate available literature of antibiotic resistances in the environment in order to give conclusions how antibiotic resistances could be included in the current guidance for the environmental risk assessment of pharmaceuticals. As a first step, the recent scientific literature on the development and/ or spread of antibiotic resistance was screened for the occurrence of adverse effects of antibiotic resistance in the environment. The aim was to give a comprehensive overview of the full range of observable effects and to identify the key parameters for the selection and dissemination of antibiotic resistance. For each individual antibiotic or class of antibiotic, respectively, the type of resistance developed and the potential for horizontal transfer of the resistance genes was recorded. In a next step, a comparison and evaluation of methods for the determination of threshold concentrations of antibiotics at which resistance is likely to be induced was conducted using available literature studies. Finally, derived thresholds from the literature were linked to consumption data for Germany to assess the probability that these concentrations might be reached in environmental compartments. The results show, that there are indications for adverse effects of the spread of antibiotic resistance in the environment. The literature review supports the requirement of including antibiotic resistance in the environmental risk assessment of pharmaceuticals. The determination of a Minimum Effect Concentration (MEC) for antibiotics can hereby be regarded as an appropriate method in order to set a threshold concentration above which the development of resistance is likely to occur in the environment and further steps should be taken.

## EP04 - Emission of chemicals from consumer goods - from emissions to effects

**EP04-1**

**Conceptualizing emissions of chemicals from products - foundations of a modelling approach**

S Molander[1], J Tivander[1], F Fuhrman[1], T Rydberg[2], PL Andersson[3], P Haglund[3], T Holmgren[3]
[1]Chalmers University of Technology, GOTHENBURG, Sweden
[2]IVL Swedish Environmental Research Institute, GOTHENBURG, Sweden
[3]Department of Chemistry, Umeå University, UMEÅ, Sweden

The research reported here is approaching the task of conceptually linking chemicals in products to their occurrence in environmental samples building on earlier work applying the concepts of substance and material flow analysis and bridging that modelling with chemical diffusive mass-transfer models. The bridging of these concepts is possible using the "combined nomenclature"(CN) and concepts such as total stock, total product area and mean composition of materials in the surface of products.

The process of conceptual modelling used builds on principles used in design of information systems in multidomain user settings. A conceptual model of the information i.e. the nomenclatures, terminologies and categorisations of concepts and terms, has been identified through workshops with researchers, a references group and a literature study.

The aim of the model is to cover the processes that lead to emissions from environmental relevant processes of products along the entire "life-cycle". The core concepts of the technical system are "product"and "use". The "product"concept hence includes any physical product not limited to a specific category. Each product consists of one or several components, which in turn are made of one or several materials, which consists of one or several chemicals. Different types of properties and descriptions are related to each of the levels of physical representation from product category (CN-categories) to chemical level.

The "use"concept is describing an episode during the "life-time"of a given product. The amount of chemical substances emitted from a product depends on the type of use, the length of time it is used in this particular way and the ambient conditions in the direct vicinity where use takes place. The use concept is thus very wide and encompasses the different stages of a product life-cycle which require a thorough definition of "use types"and ambient conditions.

A further specification of concepts has been done, covering around 20 concepts and their further relations and connections to data and data sources useful for calculations will be presented.

**EP04-2**

**Human exposure to PBDEs in Europe and North America**

N von Goetz, M Scheringer, D Trudel, K Hungerbuhler
ETH Zurich, ZURICH, Switzerland

Polybrominated diphenylethers (PBDEs) are flame retardants used to reduce the ignition and spread of fire in a broad range of products such as computer screens, mattresses, or upholstery in transport vehicles. Lower-brominated PBDEs (penta and octa mixtures) have been banned in Europe and voluntarily phased out in North America. Deca-BDE is still in use in most states of the US, but will be phased out by the end of 2013. In Europe deca-BDE is no longer used in electronics and electrical applications.

The aim of this study is to show with a consistent methodology whether the different legal settings, the different use patterns of PBDEs, as well as the differences in behaviour (e.g. eating habits) lead to different dose levels of PBDEs taken in/up by humans. The exposure was modelled probabilistically for five regions (North America, UK, Northern, Central and Southern Europe), seven consumer age groups, eight most important PBDE congeners and eight pathways (e.g. intake via food, dust, soil, and organic films).

The following results were derived: (1) Americans experience higher doses of PBDEs than Europeans. (2) Consumption of food and inadvertent ingestion of dust as well as dermal contact to dust contribute most to the exposure to PBDEs. In most cases food represents the dominant pathway for median dose estimates, whereas in the higher dose percentiles the contribution of dust becomes more important. (3) Infants experience the highest doses, followed by toddlers and children; and then teenagers and adults with about 5 times the dose of adults. This hockey-stick like dose pattern is also visible in biomonitoring data, confirming our model results.

Most likely, the reason for Americans to experience higher doses of PBDEs is that more consumer products are treated with flame retardants in North America compared to Europe. Oral uptake of food and dust and dermal uptake of dust are the most important pathways due to the persistent and bioaccumulative nature of PBDEs and their application in products that are used mainly indoors. Younger consumers take up higher doses mainly due to their higher ingestion of food and dust compared to body weight.

Using a consistent methodology we show that Americans take up higher doses than Europeans. We also show that food and dust are important sources of exposure and infants take up the highest doses. There are, however, large uncertainties associated with the oral dust intake rates and dermal uptake rates for PBDEs.

**EP04-3**

**Ecotoxicological assessment of UV filter substances**

D Kaiser, M Oetken, J Oehlmann
Goethe University Frankfurt, FRANKFURT, Germany

Chemical UV-filters are used in sun protection products and personal care products in order to protect consumers from ultraviolet (UV) radiation. Therefore, the production volume of UV-filters has increased continuously in the last decade. Prior studies have shown that UV-filters may be introduced to surface water directly via release from skin during swimming and indirectly via wastewater treatment plants from household use as well as further washing off during rainfall. Due to their physiochemical properties, UV-filters are regarded to be persistent in the environment. The occurrence of UV filters in soil and sediment has attracted much less attention compared to water bodies, and the existing studies are limited to a few filters. For this reason an analytical assessment of widely used UV filters in sediments via GC-MS was done. We found, that some of these substances tend to accumulate in sediments and are present in high concentrations during summer.

Considering this environmental exposure, there is only a limited knowledge on ecotoxicological and toxicological effects of UV-filters on aquatic invertebrates. Some in-vivo-tests with vertebrates (fish, rats, mice) and in-vitro-tests with isolated receptors and human cell lines elucidated the endocrine disrupting and toxic potency of these substances. Consequently, exposure to UV-filters may result in serious health problems for aquatic wildlife.

The study aims to evaluate the presence of the selected substances in the environment and the effects of most common UV-filters (Ethylhexyl-methoxycinnamate, Octocrylene and Butyl-methoxydibenzoylmethane) on aquatic organisms, focussing particularly on infaunal and epibenthic invertebrates (*Chironomus riparius*; *Lumbriculus variegatus* and *Potamopyrgus antipodarum*). Due to their life habits, these organisms are especially affected by lipophilic substances.

Results of the analytic and effect studies will be presented and discussed

**EP04-4**

**From sources to urban fate: a contrast of PCBS, PBDES, PAHs and synthetic musks**

L Diamond[1], PA Helm[2], SA Csiszar[1], L Melymuk[1], M Robson[1], A Giang[1], S Backus[3], B Gilbert[2], S Daggupaty[3], L Jantunen[3]
[1]University of Toronto, TORONTO, Canada
[2]Ontario Ministry of Environment, TORONTO, Canada
[3]Environment Canada, BURLINGTON, Canada

Diamond and Harrad (2009) proposed a conceptual model for human exposure to chemicals contained within a stock or inventory of materials and products. The inventory is held mainly indoors, which is the first environment into which the chemicals migrate. From indoors chemicals migrate outdoors into the urban environment. Persistent chemicals will be exported from the urban area enabling transfer through terrestrial and aquatic food webs from which the chemical may return to the urban area in foods that we eat.

To evaluate the model we quantified and contrasted the emissions, movement and inventory of 4 compounds in Canada's largest urban area, Toronto (2.5 million people). Through material flow analysis, multimedia measurements and mass balance modelling, we examined PCBs (e.g., in interior and exterior building sealants), PBDEs (in the pre-2008 electrical and electronic products, textiles, etc.), polycyclic musks or PCMs (synthetic fragrances in "down the drain"consumer products), and PAH (combustion by-products and pavement coatings).

Indoor air concentrations of PCBs, PBDEs and PCMs all exceeded those outdoors and the magnitude of outdoor air concentrations of PCBs and PBDEs corresponded to their respective spatial inventories. Modelling results showed that 85-98% of emissions are advected via air from the urban area allowing for persistent PCBs and PBDEs to enter the terrestrial food web. Measurements corroborated that a fraction of PCB, PBDE and PAH emissions enter urban soils and surface waters where the later, we postulate, originate from wash off of atmospherically deposited surface films on impervious surfaces and soil entrainment during storm events. In contrast, the fate of more volatile PCMs is controlled by waste water treatment plant discharges and atmospheric processes. Thus, PBDEs are released from indoors to the outdoor environment, from which air and surface waters deliver these emissions to the surrounding environment. PBDEs are also released from treated waste water effluent. The fate of PCBs, which have the greatest emissions in the downtown area where the largest inventory was located, is mostly controlled by atmospheric movement. PAH emissions are dominated by transfer to surface waters whereas "down-the- drain"PCMs are mostly emitted to the environment via treated waste water treatment plant discharges.

**EP04-5**

**Predictive emission model for organic compounds added to materials in consumer goods**

E Holmgren[1], L Leif[2], MU Olofsson[1], P Andersson[1], P Haglund[1]
[1]Umeå University, UMEÅ, Sweden
[2]FOI CBRN Defence and security, UMEÅ, Sweden

Additives are added to materials in consumer products to give different functions as plasticizers, flame retardants, stabilizers, and biocides and such additives may be emitted and reach the environment. Phthalates and other organic compounds are, for example, released from indoor materials and building products and found in water and sediment. Building products have long residence time and large amounts are stored in the society, which may lead to long-term release. Substances that are added in large quantities to products today and are migrating slowly might therefore become problems in the future.

The objective of this study was to develop a general model that can predict emissions of organic compounds from articles based on material properties and the chemical structure of the organic compounds.

The calculation of emissions was made with predictions of partition coefficient, diffusion coefficent and convective mass transfer coefficient and with infromation on material thickness, content and life time from The Swedish Flooring Trade Association and Swedish manufacturers of plastic flooring. Sewage sludge data originating from the Swedish annual environmental montoring program was used for modeled validation.

The model overestimated diffusion coefficient due to the conservatively set material constants. A comparison of model and experimental data for di-(2-ethyl hexyl) phthalate (DEHP) emissions from vinyl flooring showed an overestimation of 20-50%.

The substitution of DEHP with di-iso-nonyl phthalate (DINP) in the beginning of 2003 are expected to result in lower overall emissions. It is also reflected of DEHP measured in sewage sludge for the past few years (2007 to 2009). However, the predicted annual emitted mass was 4-fold less than the mass found in Swedish sewage sludge. This may indicate that other plasticizer containing materials are also emitting DEHP. The model was also used to compare future scenarios in which DINP was replaced by alternative plasticizers such as isosorbate diethylhexyl (isDEH) and di-iso-nonyl cyclohexane (DINCH) and it was shown that use of DINCH would yield lower, and use of isDEH higher, future emissions as compared to DINP.

The method developed seems to give a fairly good estimation of the emitted amounts. However, it does not take into condsideration processes such as particle-aided releases and emissions of wear particles, and cannot accurately deal with multilayer-materials. Work in these directions are in progress.

**On the lookout for microplastics in sediments and biota: exploring new techniques**

M Claessens, CR Janssen
Ghent University, GHENT, Belgium

Marine litter has been an issue of concern for decades. However, recently international attention has increased due to the fact that the annual global production of plastics is increasing and the buildup of these materials in the environment may become problematic.

Under influence of UV-light and mechanical forces, plastics also tend to break down into smaller particles in the size range of 1 mm and smaller. While no clear adverse effects of these so called microplastics on marine organisms have been reported, they have been detected in the water column and sediments at high concentrations. The most widely used method to extract microplastics from sediments is based on flotation of the plastics in a saturated salt solution. This method is not 100% efficient, as PVC for example has a density higher than that of a saturated salt solution. High density chemicals like sodium iodide (NaI) are expensive to use on a large scale. Here, a new method using a fluidized sand-bath and the use of NaI on a small scale is proposed. This technique allowed to achieve an extraction efficiency of 100% for PVC particles and 98% of fibres after one sand-bath extraction and maximally 3 subsequent NaI extractions.

Uptake of microplastics has already been observed in mussels, sea cucumbers, barnacles and other organisms during laboratory trials. For mussels for example, it has also been shown that particles smaller than 20 µm have the potential to translocate to the circulatory system. However, in field collected organisms, no evidence exists yet that microplastics are taken up inside the tissue. A method to extract microplastics - based on tissue digestion - from such organisms is proposed.

**EP05-2**

**Biodegradation in soil of an experimental polyester**

M Siotto[1], V Mezzanotte[2], M Tosin[1], F Degli Innocenti[1]
[1]Novamont S.p.A., NOVARA, Italy
[2]Univerità di Milano Bicocca, MILANO, Italy

The resistance to all form of degradation of traditional plastics allows them to be used in many applications, but their disposal contributes to increase the amount of municipal wastes. Biodegradable polymers can be used in specific applications (i.e. compostable waste bags, carrier bags, single-use tableware, mulch films) allowing to avoid landfill disposal , thus reducing the cost for waste management and the accumulation in the environment. Products used in agriculture (in particular mulch films) are applied to soil and can be left there. A biodegradable polymer is completely converted by microorganisms (under aerobic condition) to carbon dioxide, water and new biomass. Standard test methods are based on the measure of the amount of CO2 evolved in a closed or a ventilated respirometer. However, CO2 is only one component in carbon balance. The determination of biomass development and of the polymer metabolites and their fate, for example in soil, is very important in order to obtain a complete description of the process. Most commercial biodegradable plastics are made of biodegradable polyesters. In this work the mineralization of a model polyester in soil was evaluated and compared with cellulose and polycaprolactone (PCL). The tests were carried out according to ASTM 5988-96. The tested materials were added to agricultural soil enriched with compost and mineral salts and put in hermetic jars. PCL and cellulose were quickly mineralized and at the end of the test (after about five months of incubation) they reached a not well defined plateau phase. Their final mineralization was about 60% and 50% respectively. The model polyester mineralization shows a different pattern: after a lag phase around 15 days mineralization proceeded regularly till the end of the test reaching about 53%. Only half of its carbon content is converted into CO2, butanediol and sebacic acid (used for its synthesis) resulted to be completely biodegradable, with about 50% of CO2 production and 50% converted into biomass, so that it is likely that no carbon remains in soil as material residue. If normalized to cellulose (used as control because considered a fully biodegradable polymer) the polyester mineralization can be considered as 100%. Results suggest that the experimental polymer was completely biodegraded, but to complete the study a simple and reliable method to measure the biomass production should be developed and applied.

**EP05-3**

**Toxic metals derived from plastic litter in a beach**

E Nakashima[1], AI Isobe[1], S Kako[1], S Magome[2], N Deki[1], T Itai[1], S Takahashi[1]
[1]Ehime University, MATSUYAMA, EHIME, Japan
[2]Sanyo Techno Marine, Inc., TOKYO, Japan

In this study we established a novel and reliable method to estimate the total mass of beach litter and toxic metals in Ookushi beach, Goto Island, Japan. Using a balloon with an attached digital camera we measured the area of beach covered by litter, and then randomly assigned ten boxes of 2x2 m across the beach to obtain *in-situ* measurements of the litter mass per unit area. The mass (kg) of beach litter is estimated by multiplying the area ($m^2$) covered by litter with the average litter-weight per unit area ($kg/m^2$) and found as 716±259 kg from a t-test with 95% confidence limit. Among randomly collected beach litter within the square areas, plastics occupy 74% of the total mass, of which light plastics such as polyethylene (PE; 234±96 kg) are more prevalent than heavier materials. Second, the concentrations (mg/kg) of toxic metals in plastic litter are estimated using handheld X-ray fluorescence analyzer (XRF, Innov-X Systems Inc., a-6500). Toxic metals in polymers are widely used as plasticizers, catalysts, stabilizing additives, and pigments. Among various toxic metals, lead (Pb) and total chromium (Cr) are detected in PE plastic litter and their concentrations are estimated at 44.7±13.7 mg/kg and 13.7±5.5 mg/kg respectively by analyzing 432 pieces of plastic samples. We also estimate the total mass (g) of Pb and total Cr carried by PE litter by multiplying the concentration (mg/kg) with the estimate PE plastic mass (kg) over the beach and calculate as 10.4±5.2 g and 3.2±1.9 g, respectively. However, Pb and total Cr contained in PE litter occasionally exceed 100 mg/kg, that is the EU regulations on packaging and packaging waste. These toxic metals in polymers are often used as pigments and are potentially released into the beach environment during the degradation of plastics. The results of other polymers will be shown in our presentation.

**EP05-4**

**Association of TiO2-nanoparticles with small plastic fragments in beach sand at the Island Norderney (North Sea)**

EF Fries[1], JD Dekiff[1], ME Ebert[2], DR Remy[3], CZ Zarfl[1]
[1]University of Osnabrueck/Institute of Environmental Systems Research, OSNABRÜCK, Germany
[2]Technical University of Darmstadt/Institute for Applied Geosciences, DARMSTADT, Germany
[3]University of Osnabrueck/Division of Ecology, OSNABRÜCK, Germany

Titanium dioxide ($TiO_2$)-nanoparticles are added to plastics during manufacture as white pigments or UV blockers. In this study the occurrence of $TiO_2$-nanoparticles associated with small plastic fragments in the intertidal sediments at Norderney, an island situated in the German Bight in the north-west of Germany, was studied.

At two locations, N1 (N53°43.187′ E007°15.946′) and N2 (N53°43.106′ E007°17.768′), 1.9 kg of sand from each sampling site were collected directly from the surface. A method based on the separation of different dense components via floating in a saline solution was optimised and applied. The total sample volume was divided into portions of 175 g. Each aliquot was poured into a 2-L separatory funnel and filled up with 600 mL of a NaCl solution (26 % w/w). The funnel was plugged and shaken. After a settling time of 1 h the sediments and 300 mL of the solution were drained down. This procedure was repeated twice by adding 300 mL or 100 mL of the NaCl solution and draining down sediments and 200 mL or 50 mL of the solution. Finally the funnel was rinsed with 1 L of distilled water and the content of the funnel containing all less dense particles was filtered by a vacuum filtration unit with a 0.45 µm cellulose acetate filter. The filter was dried at room temperature, sealed in petry dishes and optically analysed under a stereomicroscope at 6.5-40-fold magnification.

Overall there were 24 plastic objects per 3.8 kg sand. Among the separated objects were green, blue and red fibres and blue, green or white shards. The smallest identifiable objects were a tenth of a millimetre, the biggest were 2 mm.

First results of the analyses of the microscopic plastic fragments using an environmental scanning electron microscope (ESEM) demonstrated the association of $TiO_2$-nanoparticles with some of the fragments. Based on our field data first estimates of TiO2 materials with plastic particles result in a range from 4 to 7 g ng $L^{-1}$ of sea surface .

Our results point out that plastic debris in rivers and oceans must be considered as a source of $TiO_2$-nanoparticles in the aquatic environment. Because of an enhanced density of microplastics containing $TiO_2$ an accumulation of such fragments in sedimentary habitats is expected. Our findings highlight for the first time a potential risk for marine ecosystems from $TiO_2$-nanoparticles associated with microplastics.

**EP05-5**

**Understanding leaching from plastics into the environment: lessons learned from food contact plastics use**

J Muncke
Emhart Glass SA, CHAM, Switzerland

Since the start of plastics mass production around 60 years ago the prevalence of environmental plastics debris has increased, and the extent of this contamination is gradually becoming apparent now. Due to its material properties plastic are not biodegraded. Weathering slowly leads to mechanical break-down, resulting in small plastic fragments being distributed worldwide. This observed widespread distribution of plastic fragments implies chemical interactions with the biotic and abiotic environment. While the adsorption of persistent environmental organic pollutants (POPs) to plastic particles is being studied, the release and migration of chemicals from the plastic into the environment is far less well characterized. For environmental research the rich body of literature concerning migration from food contact material (FCM) plastics into food and food simulants can be a very useful source. This paper reviews FCM plastics migration studies and highlights the presence of endocrine disrupting chemicals (EDCs) in FCM. A good understanding of plastics' qualitative and quantitative characteristics will be imperative to address environmental pollution and understand toxicity of plastic leacheate. Furthermore, plastics used to package foods and beverages constitute between 10 to 20% of all plastics currently manufactured. As single-use items the highly abundant types of plastic packaging are thought to constitute a significant fraction of marine plastics debris. A closer look at their chemical composition is useful for assessing and characterizing the nature of plastics chemical pollution.

**EP05-6**

**What do plastic additives add to life cycle assessment results?**

N Jonkers, H van Ewijk, H Krop
IVAM - University of Amsterdam, AMSTERDAM, The Netherlands

Plastics are produced in countless varieties of polymer mixtures and additives such as plasticizers, flame retardants and stabilizers. In life cycle assessment (LCA) studies, due to a lack of specific composition information it is common to reduce this complexity to the assumption that plastics are composed of pure single polymers.

The current study investigates how the calculated environmental impact of plastics would change when additives are included in LCA calculations. Several examples will be presented to illustrate the contribution of additives to the total environmental impact of plastics. The first example considers flame retardants used in plastics for electronic equipment (e.g. bisphenol-A derivatives in polystyrene blends, often present at ~20% weight). Other examples to be discussed include plasticizers and fillers, which can constitute up to 40% of the weight of the plastic. While the use of phthalates in plastics increases the potential ecotoxicological effects, the use of the filler material calcium carbonate leads to a reduction of ecotoxicological and other impacts.

The consequences of the uncertainties and variability in the detailed composition of plastics will be discussed in relation to other model uncertainties such as exposure routes of these additives to organisms in the environment (leaching from landfills, volatilization during use phase).

## ET01 - Alternatives to animal testing in ecotoxicology

**ET01A-1**

**Comparison of cartilage and bone malformations in the head of zebrafish embryos after exposure with dithiocarbamates and hydrazides**

RA Strecker, T Braunbeck
University of Heidelberg, HEIDELBERG, Germany

Dithiocarbamates such as disulfiram are well-known teratogens causing wave-like deformation of the notochord and cartilage malformation in fish embryos. Although different in chemical class, molecular weight and log KOW, hydrazides, especially acetic hydrazide, generate the same morphological effects. Similar results are also found for benzhydrazide, formic acid hydrazide and isoniazide. Fertilized zebrafish eggs were exposed for 6 days, fixed in paraformaldehyde and stained as whole mounts. Disulfiram induced strong cartilage malformations after exposure to ≥ 80 µg/L, whereas acetic hydrazide caused cartilage alterations from 1.5 g/L. Wavy notochords occurred after exposure to disulfiram even at the lowest test concentration of 20 µg/L, whereas at the two lowest concentrations of acetic hydrazide (0.375 and 0.75 g/L) mainly fractures of the notochord were observed. Concentrations of acetic hydrazide ≥ 1.5 g/L resulted in undulated notochords, similar to disulfiram. Cartilages and ossifications of the cranium, including the cleithrum, were analyzed individually assessing the severity of malformation and the degree of ossification of bones in a semi-quantitative approach. Cartilages of the neurocranium, such as the ethmoid plate, proved to be more stable than cartilages of the pharyngeal skeleton such as, e.g., Meckel's cartilage. Hence, ossification is much more susceptible to the test compounds than cartilage, showing alterations at lower concentrations, mostly as a reduction of bone mass.

**ET01A-2**

**Further development of a gene expression fish embryo test as a potential alternative to the fish early life stage test**

M Weil[1], L Vorberg[1], J Rooch[1], N Kluever[2], S Scholz[2], L Yang[3], J Legradi[3], U Straehle[3], F Sacher[4], K Duis[1]
[1]ECT Oekotoxikologie GmbH, FLOERSHEIM, Germany
[2]Helmholtz Centre for Environmental Research - UFZ, LEIPZIG, Germany
[3]Institute of Toxicology and Genetics, Karlsruhe Institute of Technology, KARLSRUHE, Germany
[4]DVGW-Technologiezentrum Wasser (TZW), KARLSRUHE, Germany

To date, there are no alternatives to chronic fish toxicity tests such as the fish early life stage test. In an earlier project, a gene expression *Danio rerio* embryo test (Gene-*Dar*T) was developed based on the fish embryo toxicity test with the zebrafish by including an additional endpoint, the analysis of differential gene expression. For most tested substances, lowest observed effect concentrations (LOECs) derived with the Gene-*Dar*T agreed reasonably well with LOECs of fish early life stage tests. However, for some substances, larger differences were observed indicating the need to improve the test protocol. Therefore, the Gene-*Dar*T protocol was further developed in the current project by identifying additional marker genes (i.e. genes that are sensitive to toxicants) and optimising the test protocol to allow an effective analysis of the larger gene set. The improved test protocol is used for testing of a range of substances.

A list of 10 model substances and 30 test substances was compiled covering different modes of action and a wide range of toxicities in the fish early life stage test. Marker genes were identified by microarray analyses following exposure of zebrafish embryos to the ten model substances and subsequent verification of sensitive genes with quantitative real time polymerase chain reaction (qRT-PCR). Eighteen genes exhibiting robust expression patterns were selected as potential marker genes. A semi-quantitative multiplex RT-PCR protocol was developed to investigate the effects of the test substances on the expression of these marker genes. This protocol has been used to study the effects of approx. 20 test substances on expression of the marker genes following exposure of zebrafish from 1 to 49 hours post fertilisation.

Range finding tests were performed with 19 test substances, definitive tests with three substances. Preliminary results indicate that substance concentrations eliciting differential gene expression deviate by factor of not more than ± 6 from the effect concentrations in fish early life stage test. Currently, the effects of further substances on differential gene expression are evaluated in definitive tests. Based on the results, the suitability of the marker genes and the correlation of the results of the Gene-*Dar*T with fish early life stage toxicity data will be evaluated. First conclusions on the application range and the limitations of the Gene-*Dar*T will be drawn.

**ET01A-3**

**Danio rerio embryos as a convenient animal alternative model for neurotoxicity assessment**

E Muth-Köhne[1], V Delov[1], A Wichmann[1], V Schiller[1], C Schäfers[2], M Fenske[1]
[1]Fraunhofer Institut für Molekularbiologie und Angewandte Oekologie IME, AACHEN, Germany
[2]Fraunhofer Institute for Molecular Biology and Applied Ecology IME, SCHMALLENBERG, Germany

The developing nervous system is far more sensitive to injury caused by neurotoxic substances than is the adult one. This conflicts with the growing number of chemicals released into the environment deemed to be neuroactive. Despite the relevance of neurotoxic effects in the hazard evaluation of chemicals, testing for neurotoxicity is currently only based on expensive, time-consuming and ethically disputed mammalian experiments, which are also unsuitable for large scale screening applications. Moreover, the present testing approaches endorsed by the OECD or the US-EPA, focus on the assessment of the human health risks only, while the environmental relevance of the neurotoxic compounds remains disregarded. In ecotoxicology, the zebrafish embryo test (zFET) has long been used as an alternative to acute and developmental fish toxicity, and there is good evidence suggesting that the embryos may also qualify as promising animal alternatives in neurotoxicity testing. The UNIFISH project tests the applicability of the zebrafish embryo assay as a screening tool for neurotoxic chemicals by pursuing an approach, which combines morphometric with immunobiochemical endpoints. Fish embryos were exposed to thiocyclam, cartap, and disulfiram for 48 h and subsequently, whole-mount immunostaining with the neuron-specific antibodies znp1 (primary motor neurons) and zn8 (secondary motor neurons) was applied. It was possible to link neuronal defects to a characteristic morphological phenotype of the embryos after the exposure. The quantification of the neurotoxic defects was based on a specified classification system, whereby the severity of neurotoxic damage to individual motor neurons can be assessed. The comparison of the EC50 values determined for neurotoxicity effects and by standard zFET displayed a good correlation between the two test systems. Therefore, the zFET for neurotoxicity could be a sensitive, convenient and reliable alternative approach to assess the neurodevelopmental hazard of environmental chemicals.

**ET01A-4**

**Transgenic fluorescent zebrafish- a promising tool to refine the zebrafish embryo toxicity test zFET**

V Delov, E Muth-Köhne, A Wichmann, V Schiller, M Fenske, C Schäfers
Fraunhofer Institute IME, AACHEN, Germany

The fish embryo toxicity test zFET is highly attractive as an animal alternative testing approach in ecotoxicology. To date, the application of the zFET has focused on acute toxicity assessment, but there is plenty of evidence for its high potential to also evaluate specific and even chronic toxicity like teratogenicity or endocrine disruption. This, however, requires a refined endpoint evaluation using detailed morphological and submorphological analysis methods, which are so far neither established nor standardised. For screening, the zFET procedures will also need adjustments to high throughput applications. The use of gene expression markers can be instrumented for a better understanding of adverse effect mechanisms. They can also help to increase the sensitivity and specificity of the zFET in comparison to the solely on macroscopic morphological endpoints based original test assessment.

This project is aimed to prove the suitability of a transgenic zebrafish line for the zFET to test chemical toxicity on vasculogenesis. The transgenic line Tg(fli1:EGFP)y1 expresses enhanced green fluorescent protein (EGFP) in the vasculature under the control of the fli1 promoter. Fli1 belongs to the ETS transcription family and is crucial for the development of the vascular system. Thus, fli1 driven EGFP-expression may serve as a relevant marker for the detection of vascular defects.

For this proposal zebrafish embryos of the Tg(fli1:EGFP)y1 line and the wild type strain were exposed to triclosan, genistein, fenazaquin and cartap for 48 h. By using a fluorescent signal based assessment method, adverse effects on vasculogenesis could be detected earlier or even at all in the Tg(fli1:EGFP)y1 embryos than in the wild type embryos. Fli1 is one of the first ETS transcription factors, and the onset of Fli1- expression in the developing endothelial vessels is as early as 14 hpf. Hence, the fluorescent assessment enables an earlier and more sensitive detection of vasotoxicity than in wild type zebrafish embryos. The transgenic zebrafish line Tg(fli1:EGFP)y1 is a promising tool to refine the zFET for vasotoxic substances.

**ET01A-5**

**Evaluation of the toxic potential of 34 organic chemicals towards a rainbow trout gill cell line**

K Tanneberger[1], M Knöbel[1], FJM Busser[2], JLM Hermens[2], K Schirmer[1]
[1]Eawag, Swiss Federal Institute of Aquatic Science and Technology, DUEBENDORF, Switzerland
[2]Institute for Risk Assessment Sciences, Utrecht University, UTRECHT, The Netherlands

The EU regulation REACH requires that all chemicals produced or imported into the EU need to be tested with respect to their impact on human health and the environment. At a production volume of 10 tonnes per year the test for acute fish toxicity (OECD 203) is obligatory. This test uses death as endpoint and requires a substantial number of fish. It is expected that in the first 10 years of REACH alone, 4.4 million fish will be needed. Therefore the development of appropriate alternative methods is timely. One promising approach is the use of fish cell lines; however, several studies indicated that fish cell lines appear less sensitive than fish. During the project CEllSens (funded by CEFIC-LRI/UK-DEFRA), we optimized the fish cell line approach; we used several steps to increase the sensitivity of the *in vitro* assay. These included the selection of the fish cell line, modification of the exposure medium, selection of toxic endpoints and the determination of the chemical bioavailability. We further showed that the chemical toxicity is also dependent on the solvent and dosing procedure. Based on these findings, we designed dosing and exposure protocols that account for factors otherwise compromising the *in vivo-in vitro* correlation. The optimized cell line approach was now used to screen the toxic potential of 34 industrial organic chemicals towards the rainbow trout gill cell line, RTgill-W1. The tested chemicals are part of the systematically derived CEllSens chemical list. The selected chemicals have a wide range of mode of action, physico-chemical properties and *in vivo* fish toxicity values. Results indeed reveal a good agreement of the acute fish toxicity data and the gill cell cytotoxicity values. Outliers from the *in vivo-in vitro* correlation can be explained by the mode of toxic action. The compounds that give the greatest deviation of *in vivo* and *in vitro* values are either neurotoxicants or need to be biotransformed into more toxic metabolites. Therefore it can be concluded that these mode of actions are not mimicked by the gill cells. By combining our results with our methods we aim to propose a strategy to use fish cell lines as surrogates for acute fish toxicity studies.

**ET01A-6**

**Combined toxicity of estrogen receptor agonists and antagonists in a fish in vitro assay**

K Petersen, KE Tollefsen
NIVA, OSLO, Norway

Primary hepatocytes from fish such as rainbow trout (*Oncorhynchus mykiss*) represent a well-characterised high-throughput screening tool for single chemicals and mixtures. These native cells provide assessment of multiple mode of action (MoA) and has successfully characterised the potency of both estrogen receptor (ER) agonists and ER antagonists *in vitro* through use of the estrogenic biomarker vitellogenin (Vtg). Fish in the environment are continually exposed to a mixture of chemicals and the growing concern about the combined effect of mixtures has resulted in development of prediction models for the combined effect of mixtures. Two of these prediction models, the concentration addition (CA) and the independent action (IA) prediction models are widely applied for direct endpoints, like *in vivo* induction of cellular reponses such as the estrogenic biomarker Vtg and *in vitro* activation of the ER. The present work assess the CA and IA prediction models's ability to predict the combined effect of mixtures of ER agonists and antagonists in a primary culture of rainbow trout hepatocytes. The ER agonists showed a concentration dependent increase in the ER-mediated Vtg production, whereas the ER antagonists showed a concentration-dependent inhibition of the estrogen-induced production of Vtg. Mixtures of ER agonists were designed based on the CA prediction model, and experimental results were compared to the predicted respons. Except for deviations from the prediction models at the higher relative mixture concentrations of the ER agonist mixtures, our results are in agreement with other *in vitro* and *in vivo* studies where CA has shown to accurately predict the combined effect of estrogen agonists. Our results show that the use of *in vitro* native cells such as primary rainbow trout hepatocytes in combination with mixture toxicity prediction models may become useful tools in assessing the combined effects of ER agonists and ongoing studies with ER antagonists will determine whether the prediction models are able to successfully predict more complex MoA such as that caused by ER antagonists.

A significant amount of current research in risk assessment of chemicals is targeted to evaluate alternative test methods that may replace, reduce, or refine (3Rs) the use of animals, while ensuring human and environmental health and safety. In 2009, the US EPA began implementation of the Endocrine Disruptor Screening Program which includes Tier 1 screening assays in fish and frog species which are closely aligned with the OECD test guideline series 229 and 231. However, these assays use a large number of animals and are quite long in duration relative to an ideal screening assay. As the Tier 1 assays screen and prioritize a large number of chemicals for possible endocrine activity shorter-term and alternative to animal tests would be advantageous. In order to identify potential alternatives, a literature search was conducted and a database with alternatives to fish and frog tests testing methodologies assembled. Data from 1995 to present were collected related to the detection/testing of estrogen-, androgen-, and thyroid-active chemicals in the following test systems: cell lines, primary cells, fish/frog embryos, yeast, bacteria, cell free systems, and "omics"technologies. A critical analysis was performed to (1) determine the strengths and limitations of each alternative assay identified and (2) present conclusions regarding chemical specificity, sensitivity, and correlation with in vivo data. A summary of the most promising alternative assays will be presented.

**ET01B-2**

**Exploring the potential of the ZFET beyond acute toxicity**

M Fenske[1], E Muth-Köhne[1], V Schiller[2], V Delov[2], A Wichmann[3], CAE Turner[4], R Kriehuber[5], C Schäfers[1]
[1]Fraunhofer Institute for Molecular Biology and Applied Ecology IME, AACHEN, Germany

[5]Forschungszentrum Jülich GmbH, Department of Safety and Radiation Protection, JÜLICH, Germany

In terms of fish toxicity test alternatives, the fish embryo toxicity test FET can certainly be considered the most promising approach, and in the context of the OECD Test Guideline Program, the FET with zebrafish (zFET) is being validated as a replacement for the fish acute toxicity test. Meanwhile, the applicability of the FET to also evaluate specific, non-acute toxicity and teratogenicity or to predict chronic adverse outcome pathways, is widely acknowledged. A prerequisite to take full advantage of the potential of the FET, however, is to agree on common standard protocols for specific applications and to address sources of uncertainty of the test procedures. In our studies, we address basic FET related methodological issues like the selection of test vessels or the test duration, to facilitate standardisation and prevalidation of the assay, but also seek to refine the FET through the integration of additional toxicological endpoints. One focus is on trancriptomics as an endpoint and the evaluation of its value to inform on underlying mechanism of toxicity. Several fish embryo studies with zebrafish were conducted either following the DIN/ISO test guidlines or following a prolonged test protocol, which includes post-hatch stages until 120 hpf. The objectives of these studies were e.g. to investigate i) the differences between the two different well-plate types and the influence of the oxygen saturation, ii) the influence of organic solvent use on the toxicity of a test compound and on the transcriptome, iii) how genistein affects gene expression and whether the estrogenic mode of action can be discerned from the transcriptome response. The results demonstrate, among other things, that oxygen can become a limiting factor in an extended FET if the test protocol is not adjusted and that the use of the organic solvent dimethylformamide (DMF) can modulate gene expression of thousands of genes. Genistein enhanced the expression of mainly estrogenic genes, which also respond in medaka and adult zebrafish. Our studies show that the ZFET has excellent potentials for application beyond acute toxicity, but for regulatory acceptance effective measures to minimise the level of uncertainty of in particular, integrated molecular omics-based methodologies are still lacking.

**ET01B-3**

**Using a toxicological model for hypothesis testing of aquatic toxicity data**

LS Mccarty
L.S. McCarty Scientific Research & Consulting, NEWMARKET, Canada

<style type='text/css'>p { margin-bottom: 0.08in; }</style>
<p style='margin-bottom: 0in;'><font size='3'>The validity, utility, and applicability of toxicity test results from standard testing protocols is contingent on whether the employed toxicological model and assumptions are appropriate and sufficient. As an initial attempt to determine the possible consequences of the lack of toxicological model specification and validation the standard 96 h acute toxicity test protocol was subjected to hypothesis testing of the enabling assumptions. A one-compartment, first-order kinetics model was specified as the toxicological model. The first assumption was that a steady-state LC50 must be either be reached or estimated from the observed data. The second assumption is that a constant time to achieving the LC50 is most appropriate. A subset of the U.S. EPA fathead minnow 96 h acute toxicity database was employed. Approximately 8% of the over 350 tests examined failed the first validation step as steady-state was not reached and could not be estimated. The remainder of the test results failed the second validation step as the time to achieve LC50 was not constant at 96h but varied widely, by a factor of over 2000 times. Using exposure-based dose data from unvalidated and uncorrected toxicity test results can introduce substantial variability/uncertainty in estimates of relative toxic potency, even with a single test protocol with a single species from the same laboratory. Formal adoption of explicit specification of toxicological model and associated assumptions, combined with routine validation, as is currently done for the statistical component of toxicity testing, is clearly required to improve the interpretation of toxicity testing data and enhance its use in estimation of both hazard and risk. </font>

**ET01B-4**

**Characterization of test conditions of the OECD 210 fish early life stage test**

SE Belanger[1], JT Oris[2]
[1]Procter & Gamble, CINCINNATI, OH, United States of America
[2]Miami University, OXFORD, OH, United States of America

A long term need in animal alternatives research is to address chronic fish toxicity. The complexity of chronic endpoints, such as growth, survival and reproduction, make this especially challenging because the "endpoint"of interest integrates a wide variety of biochemical, physiological, behavioural and ecological factors. To better define the target for 3R activities, we initiated a systematic assessment of current fish chronic toxicity tests. The Fish Early Life Stage Test (OECD 210, FELS) is the most commonly used ecotoxicity test to develop estimations of effects from long term exposure of fish to chemicals. As part of a larger effort to understand the statistical power of the OECD 210 FELS test, we summarized >100 FELS studies. In addition to power analyses, the data set was probed for the general ability of laboratories to meet control performance criteria (minimum levels of viable eggs, control survival). The data set provides an opportunity to assess the breadth of known test conditions and probe relationships with control performance, test outcomes, and species-specific tendencies in conducting OECD 210 tests. The database includes relevant information such as test durations, temperature, conductivity, pH, hardness, analytical verification of exposure, type of exposure system, use of solvents, and effect concentrations. This paper provides an overview of the characteristics of test conditions commonly encountered in the OECD 210 FELS Test. A total of 89 chemicals in 109 FELS from 15 laboratories studies were reviewed. Fathead minnow studies were most common (72%), followed by zebrafish (12%) and rainbow trout (12%). Test temperatures and dissolved oxygen recorded during tests span a fairly significant range. All studies met the minimum DO saturation requirement (60%) although studies at the low end of percent saturation were associated with the lowest length and weight and had acceptable, but marginal, percent survival. Approximately 50% of studies did not define a LOEC while 65% of the time an EC10 was obtained. Low statistical power associated with low replication in the FELS has been noted. Test conditions were most variable for the fathead minnow whereas Zebrafish and rainbow trout studies appeared to be more tightly controlled. The OECD 210 Guideline does not provide detailed guidance on several aspects of the tests which provides opportunities for diverse interpretations which could be rectified in a careful updating of the guideline.

**ET01B-5**

**Evaluation of the OECD 210 Fish Early Life Stage Chronic Toxicity Test - Setting the Target for Future Animal Alternative Efforts**

JT Oris[1], SE Belanger[2], AJ Bailer[1]
[1]Miami University, OXFORD, United States of America
[2]The Procter & Gamble Co., CINCINNATI, OH, United States of America

Several promising animal alternatives approaches now exist for acute fish toxicity and bioaccumulation. In the context of international chemical management programs a larger need now looms to address chronic fish toxicity alternatives. Many obstacles need to be overcome to make chronic ecotoxicity alternatives a reality; however, a fundamental tenet of any approach should be that the alternative should not increase uncertainty in hazard and risk assessment. Therefore, understanding the present level of uncertainty in identification of hazards based on traditional assays sets the bar for future alternative developments. The chronic fish toxicity assay most commonly used to establish chronic effects is the OECD 210, Fish Early Life Stage Test. We have collated a database (>100 studies and compounds from 15 different laboratories) to probe the data characteristics of the OECD 210. Studies were constrained to fathead minnow (72%), rainbow trout (12%) and zebrafish (16%), which form the majority of studies in the past three decades. Studies were summarized with respect to experimental design, water quality, quantifying chemical exposure, and measured test endpoints (hatchability, post-hatch survival, wet and dry weight, length, developmental abnormalities). Information was collected at the level of individual replicates with the goal of determining the statistical power of the reviewed studies to detect biologically meaningful effects. Results of the analysis indicated that improvements in the sensitivity of the test could be made by maximizing the number of replicate chambers per treatment concentration rather than by maximizing the number of organisms per chamber, by increasing the acceptable level of control hatching success and larval survival compared to current levels, by using wet weight measurements rather than dry weight, and by focusing test effort on species that demonstrate less variability in outcome measures. Effects endpoints were represented primarily as NOECs and less often as EC10 or EC20 values. From these analyses we provide evidence to support the level of uncertainty and power to expect from traditional OECD 210 studies as a target for future animal alternative methods for chronic toxicity testing in fish.

An integrated Fish Testing Framework project was initiated in 2009 as OECD Project 2.30 with the US as the lead country. The objectives were to review regulatory needs and data requirements for fish testing and review the currency of existing OECD Test Guidelines. In addition, the project aimed to support animal welfare concerns by identifying unnecessary test methods, minimizing the number of *in vivo* tests, and ensuring the optimal use of data derived from *in vivo* studies. A fall 2010 workshop with participation from ~40 experts was organized with the goal of producing a guidance document that provides a detailed discussion of issues, relevant endpoints, and considerations for a harmonized testing framework for fish. In addition to reviews of OECD fish test guidelines, topic areas included general test methods, regulatory needs & data requirements for fish testing, statistical considerations, animal welfare considerations and alternative approaches to testing. General guidance on strategies for approaching hazard testing with fish was developed by building broad principles to guide testing which can be adapted for specific circumstances and types of chemicals.
Preliminary recommendations focused largely on revisions to existing TGs and/or the need for expert group discussions, workshops, or reviews to address critical issues. Existing TGs that warrant revision and updating include TG210 and TG203. Several other TGs (212, 215) may require updating upon completion of the Fish Embryo Test validation. TG204 was recommended for deletion. Several issues necessitate expert working groups, workshops, or review papers before any revisions can be made including: evaluation of solvent effects; choice of test concentrations for fish endocrine screening assays; test acceptance & validity criteria; water & nutrition quality; review & analysis of existing fish data to further inform TG229 development; development of high-quality fish chronic data sets; review of practical applications of mode of action; assessment of the appropriateness of the various recommended or optional fish species in TGs; and harmonization of definitions across various TGs. This presentation will highlight the conclusions and recommendations and discuss the developed framework document.

## ET02 - Assessing the exposure, effects and risks of Pharmaceuticals and Personal Care Products (PPCPs) in the environment

**ET02A-1**

**Comparing prioritisation schemes for environmental risk assessment of human pharmaceuticals**

V Roos[1], J Fick[2], L Gunnarsson[3], DGJ Larsson[3], C Rudén[1]
[1]Royal Institute of Technology (KTH), STOCKHOLM, Sweden
[2]Umeå University, UMEÅ, Sweden
[3]The Sahlgrenska Academy at the University of Gothenburg, GÖTEBORG, Sweden

The presence of pharmaceuticals in the aquatic environment, and the concerns that these pharmaceuticals might negatively affect aquatic organisms, has gained increasing attention over the last years. Ecotoxicity data are lacking for most pharmaceuticals and it is therefore important to prioritise pharmaceutical substances for ecotoxicity testing and environmental monitoring. An ideal prioritisation procedure would be systematic, transparent, based on relevant data and applicable to every API on the market.

In the present study, we have ranked aproximately 600 active pharmaceutical ingredients (APIs) currently on the Swedish market according to chemical, environmental effect, sales, and pharmacological data, and combinations thereof, with the aim to discuss the consequences and implications of using different parameters for ranking pharmaceuticals. Particular focus is put on the fish plasma model, originally proposed by Huggett et al (Hum Ecol Risk Ass 2003;9:1789-1799), and its application by the MistraPharma research programme in which we participate. The fish plasma model estimates fish plasma concentrations of pharmaceuticals based on PEC and lipophilicity (logP) values and compares the predicted fish blood plasma levels to human therapeutic plasma levels, thereby creating a concentration ratio (CR).

The fish plasma model takes into account both the estimated internal exposure at the drug target(s) and an estimate of potency (based on read-across from humans, i.e. data that are available for most pharmaceutical substances). This makes it a theoretically attractive concept for predicting risks for pharmacological effects in fish, whether adverse or not. We would like to stress, however, that any prioritisation scheme should be evaluated empirically for accuracy prior to implementation. A comparison of predicted or measured fish plasma levels and human therapeutic levels correctly identifies ethinylestradiol and levonorgestrel as pharmaceuticals of high environmental risks. This adds confidence to the overall concept of the fish plasma model.

**ET02A-2**

**Perspectives on prioritization approaches for studying pharmaceuticals in the environment**

BW Brooks[1], JP Berninger[1], ABA Boxall[2]
[1]Baylor University, WACO, United States of America
[2]University of York, YORK, United Kingdom

Human and veterinary pharmaceutical residues in the environment have received unprecedented attention from citizens, environmental scientists, engineers and managers, and regulatory authorities over the past decade. An increasing body of literature is reporting the accumulation of therapeutics in wildlife, though an understanding of relationships among internal exposure, therapeutic mechanisms/modes of action and adverse effect thresholds is lacking. Further, some of the unique properties of pharmaceuticals present unique challenges to the assessment of environmental risk and hazard. Fortunately, pharmacological safety data is often more available than many other classes of industrial chemicals, which allows for physical-chemical and biological read-across applications among target and non-target organisms. Various efforts have attempted to identify pharmaceutical properties associated with greater risk to aquatic and terrestrial organisms. In this presentation we critically review such approaches for developing prioritization hazard and risk frameworks in prospective and retrospective environmental assessments. Because secondary poisoning of diclofenac represents a definitive example of wildlife impacts by a pharmaceutical, we specifically examined the potential for secondary poisoning to terrestrial wildlife using a trickling filter case study. Herein we accounted for the influence of pH on partitioning of weak acids and weak bases to predict relationships between oral wildlife exposure and recommended daily dose in humans. We then assessed these high priority pharmaceuticals for side effects and common contraindications, and further examined their potential hazards to aquatic life. This study thus provides a novel approach for considering aquatic and terrestrial receptors for prioritizing environmental risk and hazards of human and veterinary medicines.

**ET02A-3**

**Human health risk assessment of pharmaceuticals in Chinese drinking water**

HW Leung[1], L Jin[2], MB Murphy[2], B Chou[3], PKS Lam[2]
[1]City University of Hong Kong, HONG KONG, Hongkong
[2]State Key Laboratory in Marine Pollution and City University of Hong Kong, HONG KONG, China
[3]State Key Laboratory of Freshwater Ecology and Biotechnology, WUHAN, China

Pharmaceuticals are a class of emerging chemicals that are of environmental concern due to their inherent bioactivity. Their ubiquitous occurrence in various environmental compartments and their effects on non-target organisms are well documented. Pharmaceutical residues and metabolites may contaminate potable water sources after being released into surface waters or groundwater, passing unchanged through drinking water treatments and ending up in tap water, where they may pose a chronic hazard to human health. However, regulatory levels for pharmaceuticals in potable water have not been established anywhere in the world. In China, existences of pharmaceuticals in sewage, surface water and sediment were previously reported but related studies in drinking water are scarce.

In this investigation, tap water was sampled from ten cities in China"'Hong Kong, Macau, Wuhan, Shanghai, Xiamen, Shenzhen, Yahcheng, Guangzhou, Nanjing, and Changsha"'during September and November, 2010. Tap water samples were collected from different individual residences spread throughout a city (n=5 per city). A total of 38 pharmaceuticals, including antibiotics, non-steroidal anti-inflammatory drugs (NSAIDs), beta-blockers, lipid regulators, psychiatric drugs, cardiac drugs, diuretic drugs and anti-hypertension drugs, were analyzed by solid phase extraction (SPE) and high-performance liquid chromatography coupled with tandem mass spectrometry (HPLC-MS/MS). Preliminary results from six cities (n = 30) showed that 16 compounds were present at detectable concentrations in at least one drinking water sample among the six cities. Of all of the detected pharmaceuticals, caffeine and salicylic acid were predominant, occurring in over 90% of the analyzed samples, followed by carbamazepine and erythromycin-H2O. To assess possible risks on human health, acceptable daily intake levels obtained from the available literature or derived from animal toxicity data, ingestion rate and exposure period will be applied to the pharmaceutical levels measured in the drinking water samples.

**ET02A-4**

**Developing environmental assessment regulations for pharmaceuticals: a drug's character is its fate**

AGM Rattray, RG Stringer, A Beck
Health Canada, OTTAWA, Canada

While timely access to pharmaceuticals and health care products is of utmost concern to the government of Canada, there is growing recognition and concern that substances in these types of products are being found in the environment in concentrations that may pose a risk. The Canadian Environmental Protection Act (CEPA) 1999 requires that all new substances for use in Canada be evaluated for their potential risks to the Canadian environment and human health. Currently substances in products regulated by the Food and Drugs Act (F&DA) (including therapeutic drug ingredients) are legally obliged to undergo an environmental assessment. However the current environmental assessment regulations were developed primarily for industrial chemicals and are not appropriate for assessing the potential environmental risk of the types of substances and release scenarios associated with drug products. As such, Health Canada, in consultation with representatives from industry, non-governmental organizations and consumer groups, initiated a project to develop Environmental Assessment Regulations (EARs) with specific information requirements for these types of substances. A framework has been developed which seeks to align with the drug development process while leveraging a testing strategy that considers the potential fate and exposure profile of the drug substance to direct the type of ecotoxicological testing to be required.

The starting premise in the development of a regulatory framework for drug substances is that the regulatory requirements must be science-based and in proportion to potential for risk and allow for the continually expanding knowledgebase of the behaviour of active ingredients in the environment to refine requirements for environmental assessments. Action limits and data requirements should be commensurate with the characteristics of the compound and its expected release into and fate in the environment. Fate/exposure directed toxicity testing ensures that all compartments of the environment are considered and will be protected, allowing the science to establish testing requirements, rather than being driven by prescriptive measures. This talk will explore some of these concepts.

**ET02A-5**

**Multi-biomarker approach to assess sub-lethal effects induced by a mixture of three common non-steroidal anti-inflammatory drugs (NSAIDs) on the zebra mussel (Dreissena polymorpha)**

M Parolini, AB Binelli, AP Provini
University of Milan, MILAN, Italy

Pharmaceutical compounds are an emergent class of environmental pollutants included in the broad category of PPCPs (pharmaceutical and personal care products). Among these, non-steroidal anti-inflammatory drugs (NSAIDs), the sixth most sold drugs worldwide with an estimated annual production of several kilotons, are commonly revealed in aquatic ecosystems in the high ng L-1 to low µg L-1 range. Some studies investigated the acute toxicity of the most common NSAIDs on non-target organisms, but the information on their capability to induce chronic effects is completely inadequate. Few investigations have only evaluated the potential toxicity of single molecules, excluding the major environmental problem due to drug mixtures. This work deals with the assessment of sub-lethal effects induced by three concentrations of a mixture of three common NSAIDs, namely diclofenac, ibuprofen and paracetamol, on the freshwater bivalve zebra mussel (*Dreissena polymorpha*). Our goal was reached by a multi-biomarker approach in order to highlight cyto-genotoxic effects, as well as the unbalance of the oxidative status of treated-specimens. The single cell gel electrophoresis (SCGE) assay, the DNA Diffusion assay, the micronucleus test (MN test) and the Neutral Red Retention Assay (NRRA) were applied on mussel haemocytes as cyto-genotoxic biomarkers. In addition, the activity of catalase (CAT), superoxide dismutase (SOD), glutathione peroxidase (GPx) and glutathione S-transferase (GST) was measured in the cytosolic fraction extracted from a pool of bivalves to reveal a possible oxidative status unbalance.

Each mixture concentration was able to induce a significant increase of primary genetic damage, which preluded fixed genetic injuries, as highlighted by the increase of both apoptotic and micronucleated cells. Notwithstanding, an unexpected reduction of DNA damage was found at the end of exposure at each concentration. In addition, the NRRA showed that exposure to mixture was able to cause a noteworthy increase of cellular stress in bivalves, above all at the highest concentration, probably due to the rise of oxidative stress, as pointed out by the unbalance of oxidative status of treated specimens. Considering the high potential toxicity of NSAIDs mixture on *D. polymorpha* further in-depth analyses should be necessary in order to investigate the involved mechanism of action and enlarge the knowledge on this fundamental ecotoxicological topic.

**ET02A-6**

**Benthic invertebrate exposure and chronic toxicity analysis for cVMS materials - a probabilistic approach and comparison to the target lipid model**

KB Woodburn[1], DE Powell[1], A Redman[2], P Paquin[2]
[1]Dow Corning Corporation, MIDLAND, United States of America
[2]HydroQual Inc., MAHWAH, NJ, United States of America

Lipophilic chemicals, such as the cyclic volatile methylsiloxane materials octamethylcyclotetrasiloxane (D4) and decamethylcyclopentasiloxane (D5), adsorb extensively to particles and surfaces in aqueous systems, making sediments a key sink when performing risk assessment evaluations. A widely accepted step for estimating the possible risk posed by such chemicals to sediment-dwelling species is to compare the observed sediment concentration with either published ecotoxicity guidelines or to chronic no-observed effect concentrations (NOECs) from toxicity testing with benthic invertebrates. The comparison of field concentrations with chronic NOEC levels can be done with simple worst-case simulations or using a probabilistic distribution approach. In this work, a comparison was made using probabilistic methods of D4 and D5 residues from sediments and organisms collected in the United States (Lake Pepin, Minnesota) and Norway (Inner Oslofjord) to chronic NOEC values determined using EPA/OECD test species such as Chironomus tentans, Chironomus riparius, Hyalella azteca, and Lumbriculus variegates; both sites are downstream from municipal wastewater treatment plants, the likely sources of the D4 and D5 residues. The risk assessment was extended using ecotoxicity data on more than 50 species using the target lipid model (TLM), which assumes a narcotic mode of action (MOA) for ecotoxicity. Comparisons were made using sediment levels on a dry weight and organic carbon basis, and with organism residues on a lipid-adjusted basis. Probabilistic endpoints of 95% exposure and 5% chronic NOEC were extrapolated from the data, which were fit using log-normal assumed distributions. The cVMS acute-to-chronic ratios (ACRs) were consistent with TLM data and with a narcosis MOA (average 2-5). Using either probabilistic techniques or the TLM database, field D4 and D5 concentrations were far below chronic threshold NOEC values with benthic invertebrates, therefore very limited risk appears to exist for benthic invertebrate species with these materials; this evaluation is based on both sediment- and tissue-based analyses and also leveraging the TLM database and narcotic MOA for cVMS materials.

**ET02B-1**

**Bioaccumulation and molecular effects of the contraceptive hormone levonorgestrel in the non-target organism Dreissena polymorpha**

V Contardo-Jara[1], C Lorenz[1], S Pflugmacher[2], G Nützmann[1], W Kloas[1], C Wiegand[3]
[1]Leibniz-Institute of Freshwater Ecology and Inland Fisheries, BERLIN, Germany
[2]Institute of Technology, Dpt. of Ecological Impact Research and Ecotoxicology, BERLIN, Germany
[3]University of Southern Denmark, Institute of Biology, ODENSE, Denmark

There is increasing concern about the adverse effects of contraceptive steroids found in wastewaters worldwide. Levonorgestrel (LNG), a synthetic steroid used as a contraceptive, as well as a post-coital contraception modality, has been detected in the effluent of STP, in surface waters, in ground water and in sediment. The effects of LNG on invertebrates, in particular on mussels are as yet unexplored. The species Dreissena polymorpha was depicted as a model organism to study adverse effects of LNG on mussels. It was the aim to explore to which extent LNG bioaccumulates in D. polymorpha, thus the bioconcentration factor (BCF) was assessed and to examine if LNG has a direct effect on cell functions of biotransformation, elimination, prevention from oxidative stress and protein damage.
Mussels were exposed for seven days in the flow-through system to increasing concentrations of LNG: 0, 0.3, 3 and 6 µg $L^{-1}$. Gill and digestive gland tissue were sampled after 1, 4 and 7 days of exposure. Real-time PCR assays were run to study changes in mRNA levels. Whole tissue was sampled at each time point for analysis of LNG tissue content. LNG water and tissue concentration were determined by LC-MS/MS.
Within four days mussels exposed to 0.3 µg $L^{-1}$ LNG bioaccumulated the substance 95-fold. Mussels exposed to the higher concentrations displayed lower BCFs (30 and 56, respectively). After one week, amounts of LNG in mussels exposed to the two lower concentrations were even increased. Only for the highest concentration a decrease of the BCF within one week could be observed.
After only one day we found an immediate up-regulation of pi class glutathione S-transferase (piGST) in both examined tissues in all treatment groups, indicating phase II biotransformation processes. Also superoxide dismutase (SOD) and metallothionein (MT) mRNA was significantly up-regulated after only one day in the digestive gland hinting on oxidative stress. After four days we found an up-regulation of P-glycoprotein (P gp), as well as increased levels of SOD and MT mRNA in mussels exposed to the highest concentration, suggesting enhanced elimination processes and ongoing oxidative stress. After one week exposure to LNG enhanced elimination processes were indicated for mussels exposed to the highest concentration also by the up-regulation of P gp in gills. An enhanced requirement for protein repair, transport or protective processes was evidenced by hsp70 induction in gills.

**ET02B-2**

**Do nonprescription pain relievers have endocrine disrupting potential in zebrafish (Danio rerio)?**

JE Morthorst[1], BF Lund[1], H Holbech[1], P Bjerregaard[1], A Lister[2], G van der Kraak[2]
[1]University of Southern Denmark, ODENSE M, Denmark
[2]University of Guelph, Department of Integrative Biology, GUELPH, Canada

Nonprescription pain relievers such as ibuprofen (ipren, ibumetin), acetylsalicylic acid (aspirin) and paracetamol (panodil, pinex, pamol) exert their effect by inhibting enzymes involved in prostaglandin synthesis. Prostaglandins are signalling molecules involved in induction of pain, inflammation and fever but they are also involved in various housekeeping functions like platelet aggregation and renal blood flow. Nonprescription pain relievers (mild analgesics) are used to treat pain, fever and inflammation and therefore found in most homes. Due to high consumption of mild analgesics in many industrialised countries several analgesics have been detected in waste water and surface water. In mammalian studies inhibition of prostaglandin synthesis have been found to affect steroid levels and sexual behaviour. Recently, also maternal consumption of paracetamol during pregnancy has been correlated with increased risk of cryptorchidism in newborn boys, and administration of paracetamol to pregnant dams reduced the anogenital distance of male rats.
In a set of studies we investigated the effects of prostaglandin inhibitors on sexual differentiation and reproductive parameters in zebrafish, which is a commonly used test organism in endocrine research. Sex ratio and vitellogenin levels in sexually mature zebrafish remained unchanged after exposure to acetylsalicylic acid (0.2-8.2 mg/L) and paracetamol (0.22-29.55 mg/L) during sexual differentiation. Both acetylsalicylic acid (3.8 mg/L) and ibuprofen (21-506 µg/L) reduced PGE2 levels in male and female zebrafish after short term adult exposure but steroid levels remained unchanged. Ibuprofen did not affect other reproductive endpoints except for vitellogenin levels in males. In conclusion, commonly used reproductive parameters in zebrafish do not seem to be sensitive towards prostaglandin inhibitors, but further investigations are required because the reduction of prostaglandins could influence various physiological processes.

**ET02B-3**

**Early life progestin exposure causes sterility in adult female Xenopus tropicalis frogs**

CB Berg[1], M Kvarnryd[1], R Grabic[2], I Brandt[1]
[1]Uppsala University, UPPSALA, Sweden
[2]Dept of Chemistry, Umea University, UMEA, Sweden

Levonorgestrel (LNG) is a pharmaceutical progestin commonly used in contraceptives. It has been found in the aquatic environment and shown to bioconcentrate effectively and impair reproduction in adult fish at environmentally realistic concentrations. As yet, however, there is a lack of data on toxicity of progestins in amphibians. Moreover, information on the long-term toxicity of progestins following early life exposure is scant. The aim was to characterize effects of developmental LNG exposure on sex differentiation, reproductive organ development and fertility using the model frog Xenopus tropicalis. Tadpoles were exposed to 19 or 156 ng/L LNG (0.5 or 0.06 nM, measured concentrations) via the water from shortly after hatching until metamorphosis. At metamorphosis, exposure was discontinued and effects on gonadal differentiation were assessed using a subsample of the animals. Remaining metamorphosed frogs were held unexposed for nine months, at which time reproductive organ structure, function and fertility were analysed. LNG exposure severely impaired oviduct development and fertility. All adult females (10) in the 0.5 nM group completely lacked oviducts. Upon mating with unexposed males, only one of the 11 LNG-exposed females laid a few eggs (none of which was fertilized), i.e. all LNG exposed females were sterile. All (8) control females laid fertile eggs. No effects on sperm count, sexual behaviour or fertility were observed in the males. No effects on sex ratio or gonadal histology were detected at metamorphosis but devastating effects on reproductive function were detected in adult females, emphasising the importance of investigating the long-term consequences of developmental exposure. To our knowledge this is the first study of developmental reproductive effects of progestin using an aquatic vertebrate. Considering that several progestins are found in the aquatic environment further investigation into the sensitivity of frogs to these compounds is warranted to understand the potential risk progestins pose to wild frog populations.

**ET02B-4**

**Effects of the antidepressant venlafaxine (Effexor®) on fish brain chemistry and predation behavior**

JH Bisesi, SJ Klaine
Clemson University, PENDLETON, United States of America

Antidepressants found in wastewater effluent and receiving streams have been shown to be relatively non toxic using traditional fish aquatic toxicity testing. But the psychotropic mode of action of these compounds warrants examination of the behavioral effects these chemicals may have on aquatic organisms. Previous results indicate the antidepressant fluoxetine (Prozac®), causes decreased brain serotonin levels in fish, resulting in a decreased ability to capture prey. Though concentrations required to cause this effect (low µg/L) are approximately two orders of magnitude higher than environmentally measured concentrations (low ng/L).
The antidepressant venlafaxine (Effexor®) has been found at low µg/L concentrations in wastewater effluent. It has a slightly different mode of action than fluoxetine, in that it is designed to alter brain serotonin as well as norepinephrine. The objective of this study was to determine the effects of venlafaxine on fish brain chemistry and predation behavior. A predator prey bioassay, designed in our lab, using hybrid striped bass (Morone saxatilis x Morone chrysops) as the predator and fathead minnows (Pimephales promelas) as prey, was used to test effects. Bass were exposed to venlafaxine for a period of 6 days and then allowed to recover for 6 days. During both exposure and recovery bass were fed four minnows every third day. The time to capture the minnows was quantified and compared among treatments. After each feeding event a subset of bass was removed and their brains analyzed for monoamine concentrations. Behavioral data was then correlated with brain chemistry data to determine if there was a mechanistic link between brain chemistry alterations and predatory behavior.

**ET02B-5**

**Effects of caffeine and ibuprofen in the health status of the European green crab**

GV Aguirre-Martínez, TA del Valls, ML Martín-Díaz
University of Cádiz, CÁDIZ, Spain

The constant input of pharmaceuticals to the aquatic environment has the consequence of exposing biota to unknown chronic effects, thus affecting the heath of organisms even at low concentrations (µg/L to ng/L). The aim of this study was to evaluate heath status of the European green crab C. maenas analyzing sublethal responses after exposure to different concentrations of caffeine and ibuprofen (including environmental concentrations) under laboratory conditions during one month. Sea water was spiked every two days with caffeine (0; 0.1; 5; 15; 50 µg/L) and ibuprofen (0; 0.1; 5; 10; 50 µg/L). Stock solutions of pharmaceuticals were diluted in 0.001% DMSO. Sublethal effects were first evaluated in vivo applying the lysosomal membrane stability test (LMS). Together with LMS, Phase I and Phase II detoxification enzyme activities, lipid peroxidation and DNA damage were determined in gill, hepatopancreas, muscle and gonad tissues. Results showed a dose-dependent and time-dependent effect of pharmaceuticals. Lysosomal membrane stability in crabs exposed to environmental concentrations of caffeine and ibuprofen was significantly destabilized compared to controls ($p < 0.05$) indicating general stress syndrome. EROD (ethoxyresorufin O-deethylase) and DBF (dibenzylfluorescein) enzymatic activities were significantly induced by caffeine (5; 15; 50 µg/L) and ibuprofen (5, 10, 50 µg/L) in gill and hepatopancreas tissues ($p < 0.05$) compared to control crabs. GST (glutation-S-transferase) enzymatic activity was significantly activated ($p < 0.05$) in all tissues by ibuprofen (5, 10, 50 µg/L) and by caffeine at higher concentration. Oxidative stress and DNA strand breaks showed and induction compared to controls ($p < 0.05$) in gills and hepatopancreas tissues exposed to the highest concentration of caffeine and ibuprofen. Results revealed that C. maenas exposed to environmental concentrations of caffeine and ibuprofen can develop general stress syndrome. Results indicated that LMS, Phase I, Phase II detoxification enzymes and antioxidant enzyme activities; lipid peroxidation and DNA strand breaks selected as sublethal responses, constituted suitable biomarkers in the assessment of pharmaceuticals pollution in marine ecosystems using the crab Carcinus maenas as bioindicator species.

**ET02B-6**

**Microbial degradation of gemfibrozil and naproxen drugs in a river water ecosystem**

A Barra Caracciolo, P Grenni, N Ademollo, L Patrolecco
National Research Council - Water Research Institute, MONTEROTONDO ROMA, Italy

The presence of pharmaceuticals as widespread ecosystem contaminants has increased attention among researchers, lawmakers, regulators, and the public in the last years. They continuously reach the environment owing to the lack of degradation in the wastewater treatment plant, and for this reason they are detected in aquatic environments. Their concentrations range from µg/L in the effluents from wastewater treatment plants to ng/L in surface waters. Pharmaceuticals are specifically designed to be biologically active, but there is limited understanding of their ecological effects. Consequently, there is the need to investigate on their possible interactions with non-target organisms in the environment, included microorganisms.
Microorganisms have a key role in the cycles of elements and in ecosystem energy flows and owing to their adaptability and metabolic potentiality, they are able to degrade most of xenobiotic compounds. Consequently they are essential in the overall processes that contribute to the quality state of natural ecosystems.
The present work aims to evaluate the environmental fate of two pharmaceuticals, such as naproxen (anti-inflammatory) and gemfibrozil (lipid regulator) commonly found as contaminants in the river Tiber (Italy). For this purpose, different water microcosms were set up (presence/absence of microbial community) and treated with naproxen or gemfibrozil at a concentration of 100 µg/l. Pharmaceutical degradations were assessed and bacterial community structure and function were investigated. At different times, bacterial abundance, cell viability and phylogenetic composition assessed by fluorescence in situ hybridization were analysed in water samples treated versus microbiological control (no treated water samples). Moreover, the degradations of naproxen and gemfibrozil were also evaluated in microcosms simultaneously treated with both pharmaceuticals

**ET02C-1**

**Drugs of abuse as new aquatic contaminants: cocaine effects on zebra mussel (Dreissena polymorpha)**

A Pedriali, A Binelli, M Parolini, C Riva, A Provini
Università degli Studi di Milano, MILANO, Italy

Cocaine is one of the most common illicitly used drugs and it has been recently found in several aquatic ecosystems worldwide. This drug was chosen for this research since a considerable amount of data are available for this substance concerning consumption and concentrations in waste and surface waters, which allow us to validate the proposed model. Present study is the first work to evaluate the cocaine cyto-genotoxic effects on aquatic non-target organisms, such as the freshwater bivalve *Dreissena polymorpha*. We chose three different cocaine concentrations very similar to those found in environment, in order to give information useful in the real world: 40 ng/L, 220 ng/L and 10000 ng/L. We evaluated the cytogenotoxicity in mussel hemocytes in *in vivo* experiments by the lysosomal membrane stability (Neutral Red Retention Assay), the single cell gel electrophoresis (SCGE) assay, the micronucleus test (MN test) and the assessment of the apoptotic frequency (DNA diffusion assay). The biomarker battery demonstrated a slight or moderate cyto-genotoxicity in zebra mussel hemocytes at the two lowest concentrations, but significant effects at the highest dose. This can lead to the hypothesis that, with the increasing of the exposure time, a significant increase in both the primary and irreversible DNA damage would be detected, as well as a general increase of cellular stress.

[4]CEF, COIMBRA, Portugal

The increase in human population carries with it a higher demand for food supplies which translate in higher production of farmed animals. The use of pharmaceuticals both prophylatic and therapeutically is necessary to promot animal health, but may have significant consequences to natural ecosystems. The extent of the effects of antibiotics released to the environment in non-target organisms is already under the scope of researchers but little attention has been given to primary producers such as macroalgae, which are in the bottom of the trophic webs. The present study tested the effects of two antibacterial agents, furaltadone and chloramphenicol, on the growth of Ulva lactuca. Results showed differences in growth rates when submitted to prophylactic and therapeutic concentrations (25 and 50 ug/ml, respectively) for both drugs. Therapeutic concentration showed a higher interference in growth than the prophylactic, causing its decline in the presence of furaltadone and an increased growth with chloramphenicol.The exposure of macroalgae to pharmaceuticals in the environment will have significant effects on growth that will depend on the characteristics and also on the concentrations of the chemical present.

**ET02C-3**

**In vivo experiments for the evaluation of different biomarkers and alterations in proteins expression profile of Triclosan in Zebra mussel (D. polymorpha)**

C Riva, A Binelli, M Parolini, F Rusconi, G Colombo, A Pedriali, R Zippel, A Provini
University of Milan, MILAN, Italy

Among the emerging class of environmental pollutants of PPCPs (Pharmaceuticals and Personal Care Products), one of the most widely used groups is that of antibacterial agents. While these products at low concentrations are probably not pharmaceutically active in humans, they may still be potential pollutants in aquatic environments. Triclosan (TCS, 2,4,4'-trichloro-2'-hydroxy-diphenyl ether) is one of the main known antibacterial agents and its increasing environmental levels is causing growing concern about its presence in freshwaters. In this work, we investigated the effects and the mechanism of action of the antibacterial agent Triclosan in hemocytes of the freshwater bivalve Zebra mussel (*Dreissena polymorpha*). For this purpose we used several biomarkers for in vivo experiments (96 h of exposure) carried out at three possible environmental Triclosan concentrations (1, 2, 3 nM). We used the single cell gel electrophoresis (SCGE) assay, the micronucleus test (MN test) and the measure of the apoptotic frequency (Halo assay) to measure the genotoxic potential of Triclosan, and the neutral red retention assay (NRRA) as a measure of lysosomal membrane stability to identify general cellular stress. We also evaluated the activity of enzymes related both to oxidative stress (superoxide dismutase -SOD-, catalase -CAT- and glutathione peroxidase -GPX-) and phase II metabolism (glutathione S-transferase -GST-) on the cytosolic fraction of the whole body mussels. Finally, we applied a proteomic technique in order to identify changes in protein expression profiles in the mussel gills.
We observed significant increases in all of the genotoxic biomarkers examined as early as 24 h after initial exposure, as well as a clear destabilization of lysosomal membranes, indicating that this chemical is potentially dangerous for the entire aquatic biocoenosis. A comparison of these in vivo data with existing data from in vitro experiments allowed us to suggest possible mechanisms of action for Triclosan in this bivalve. The role of the identified proteins in this mechanism of action is discussed.
Although further studies are needed to confirm the possible modes of action, our study is the first to report on the effects of this widespread antibiotic on freshwater invertebrates.

**ET02C-4**

**The impact of triclosan on ecosystem services of freshwater biofilms**

SU Gerbersdorf[1], HV Lubarsky[1], S Franz[2], G Streck[2], M Schmitt-Jansen[2], S Wieprecht[1]
[1]University Stuttgart, Institute of Hydraulic Engineering, STUTTGART, Germany
[2]UFZ Leipzig, LEIPZIG, Germany

Triclosan (5-chloro-2-(2,4-dichlorophenoxy)phenol) is a broad-spectrum antibacterial that received much attention during recent years since considerable loads accumulate in the aquatic habitats with toxic effects on bacteria and on non-target organisms. Consequently, research has been conducted on the mode of TCS action as well as on TCS impact on the growth, physiology and species composition of bacteria, microalgae and multicellular organisms such as shrimps. Since biofilms are ubiquitous members of freshwaters that provide important ecosystem services (e.g. self-purification), it is valuable to look beyond the criteria of descriptive and functional parameters.
In this paper, we investigated the impairment of the stabilisation capacity of freshwater biofilms by TCS exposure to different concentrations (2 µg/L - 400 µg/L) over time (2 weeks). Biostabilisation was determined using a new developed device (MagPI), the EPS (extracellular polymeric substances) quantity and quality was assessed and the biomass / cell numbers (microalgae, bacteria) of the microbial community determined along with its composition (microscopic analysis for microalgae, DGGE / FISH for bacteria).
The stabilisation capacity of the biofilm was impressive (up to 4 times higher than the control) but significantly impaired by the TCS exposure, showing the lowest sediment stability in the treatment with the highest TCS concentration (decrease of stability to 65% of the initial value). While the bacterial cell numbers showed first a continuous increase despite TCS spiking, bacterial growth was soon significantly hampered in the treatments with the higher TCS concentrations (85 - 400 µg/L). In the treatments with the lower TCS concentrations (2 - 25 µg/L), the bacterial growth showed a similar trend when compared to the control biofilm without TCS. These data suggest a different mode of TCS action from suppressing metabolism to bactericidal effects depending on the TCS concentration. TCS exposure clearly induced shifts within the bacterial and microalgal community that explained, along with significant changes in EPS quantity and quality over time, the observed changes in biostabilization capacity.
In summary, triclosan exposure affects more than structural and functional parameters of freshwater biofilm; in impairing the stabilisation capacity, it has a great influence on the dynamics of sediments and associated pollutants with wider implications for the aquatic ecosystems and beyond.

**ET02C-5**

**Triclosan persistence through waste water treatment plants and its potential effects on fluvial systems**

M Ricart[1], HG Guasch[1], DB Barceló[2], CB Bonnineau[1], FG Frits[3], MF Farré[2], JF Ferrer[4], ML Miquel[3], MS Morin[5], LP Proia[1], AR Romaní[1], LS Sala[6], SS Sabater[1]
[1]University of Girona, GIRONA, Spain
[2]Department of Environmental Chemistry, IIQAB-CSIC, BARCELONA, Spain
[3]Aquatic Ecology & Water Quality Management Group, Wageningen University, WAGENINGEN, The Netherlands
[4]Empresa Mixta d'Aigües de la Costa Brava, S.A., GIRONA, Spain
[5]Cemagref, LYON, France
[6]Consorci de la Costa Brava, GIRONA, Spain

Numerous chemicals are continuously released into the environment as a result of their use in industry, agriculture or household activities. The so-called emerging compounds are thought to be potential threats to environmental ecosystems. Among them, triclosan is a commonly used bactericide that survives several degradation steps in wastewater treatment plants (WWTP) and potentially reaches fluvial ecosystems. Moreover, in Mediterranean areas where water scarcity results in low dilution capacity, the potential environmental risk of triclosan increases.
A set of experimental channels was used to examine the short-term effects of triclosan (from 0.05 to 500 µg/L) on biofilm algae and bacteria. Environmental concentrations of triclosan caused an increase of bacterial mortality (EC10= 0.6µg/L). The photosynthetic efficiency of algae was inhibited (EC10= 3.4µg/L), as well as the non-photochemical quenching mechanisms (EC10= 1.3µg/L). Diatom cell viability was also affected with increasing concentrations of triclosan (EC10= 3.7µg/L).
Triclosan toxicity was also evaluated when applied in binary mixtures with i) the phenylurea herbicide diuron and ii) the pharmaceutical product propranolol (β-blocker) on the green algae Scenedesmus obliquus. The toxicity of the first mixture was accurately predicted with the current available models. However, these models underestimated the joint toxicity when triclosan was mixed with propranolol. This mixture had a greater negative impact that predicted by models, showing a synergistic effect.
Although triclosan is present at low concentrations in fluvial systems, the capacity of triclosan to survive through WWTP processes, the toxicity detected on the co-occurring non-target components (algae) of the biofilm community and the increase in toxicity when mixed with other substances demonstrates that triclosan may be toxic to fluvial communities. The results obtained highlight the need of studies covering both single exposures and mixtures in order to assess the environmental risk of emerging pollutants.

**ET02C-6**

**Tertiary treatment methods reduce the ecotoxicity of wastewater for Gammars fossarum (Crustacea, Amphipoda)**

M Bundschuh, JP Zubrod, F Seitz, R Schulz
University of Koblenz-Landau, LANDAU, Germany

Among other chemicals, pharmaceuticals and personal care products enter the aquatic environment via treated wastewater and are thus frequently detected in surface waters. Tertiary treatment methods, like ozonation, pulverized activated carbon (PAC) and titanium dioxide in combination with ultraviolet (UV) irradiation, are considered to be suitable to reduce the load of those contaminants (=micropollutants) in wastewaters. However, these treatment methods were hardly investigated regarding their potential to alter the ecotoxicity of wastewater. Therefore, we sampled secondary treated wastewater from two wastewater treatment pants (WWTPs) and treated each of the samples with these tertiary methods at the lab-scale. Subsequently, the amphipod shredder *Gammarus fossarum* was exposed to secondary treated wastewater, wastewater additionally treated with ozone, PAC or $TiO_2$ & UV, and river water (control) for seven days under laboratory conditions (n=20). Gammarids exposed to secondary treated wastewater from both WWTPs showed a significantly reduced (<50%) feeding rate compared to river water. Ozonation as well as the combination of $TiO_2$ with UV-irradiation reduced the ecotoxicity compared to secondary treated wastewater for *G. fossarum* displayed by a significantly (twofold) increased feeding rate. In contrast, the application of pulverised activated carbon in secondary treated wastewater, did not cause a significantly reduction of the adverse effects related to secondary treated wastewater. However, following the amendment of nutrients to PAC-treated wastewater the feeding rate was at the control level suggesting that activated carbon also removes trace elements from wastewater overriding the positive effect of the micropollutant removal. Finally, all three tertiary treatment methods assessed in the present study seem to be suitable to reduce the ecotoxicity of secondary treated wastewater and hence may have the potential to improve both the chemical and ecological status of surface waters as required by the Water Framework Directive.

## ET04 - Ecologically relevant endpoints

**ET04-1**

**In situ feeding assay with Gammarus fossarum: move forward to an ecologically relevant biomonitoring of water chemical quality**

R Coulaud[1], A Chaumeau[1], O Geffard[1], H Quéau[1], J Garric[1], S Charles[2]
[1]Cemagref, LYON, France
[2]Université de Lyon, LYON, France

As shown by many laboratory studies since 1990s, a large range of chemical stressors can inhibit gammarids feeding rate. Feeding inhibition also constitutes in most case one of the first traits observed in responses to environmental pollutions. Studying the effects of pollutants on the feeding behaviour is of ecological concern; as it can be related to life history traits like growth, survival or fertility thus allowing assessing the effects of toxicants on higher biological organization levels, such as population. A mechanistic modelling approach is proposed as a perspective to perform this extrapolation between biological scales.
Our work was focused on the crustacean Gammarus fossarum widely present in European rivers. In a first part, we illustrate how taking into account of the influence of biotic and abiotic factors

(body size, temperature, water hardness) on feeding activity allows one to improve the interpretation of in situ feeding rate assays for the evaluation of water quality. For this, we performed a three-steps approach: (i) we characterized the influence of these important confounding factors in laboratory conditions, (ii) we validated the robustness of feeding activity reference values; these latter were established through in situ caging experiments with transplanted standard organisms in reference streams with contrasted abiotic profiles at different seasons (iii) finally, by considering in situ caging in contaminated streams, we underlined the importance of taking into account the influence of such factors for a better toxicological bio-monitoring of freshwater ecosystems.
In a second part, we show that feeding activity can be linked to life history traits such as fecundity and we propose a modelling methodology to link impact on feeding activity to potential effects at the population level, taking into account the influence of environmental conditions. For this purpose, we developed an environmentally realistic Leslie population model, which allowed us to link individual-level demographic parameters to population dynamics. Ultimately, we illustrate how couple fitness related endpoints measured in bioassays procedures to population modelling.

**ET04-2**

**Effects at a daily resolution of imidacloprid on the individual feeding activity of Gammarus pulex (L.)**

A Agatz[1], R Ashauer[2], CD Brown[1]
[1]University of York, YORK, United Kingdom
[2]Eawag-Aquatic Research, DÜBENDORF, Switzerland

Ecosystems are usually exposed to low concentrations of toxicants. Environmentally-relevant concentrations of toxicants rarely cause mortality. Consequently, observing behavioural changes of organisms evoked by relatively short, low concentration stress in ex-situ studies is a useful tool. Differences between individuals in the endpoint of interest can be equal or even greater than the effect caused by the toxicant, making it necessary to reduce the variability by, for example, focusing on a sub-group of the test species.
A method to measure the feeding activity of Gammarus pulex on a daily basis was developed, taking into account the intraspecific variability caused by food source and infection with acanthocephalan parasites (exp.1) and body mass (exp.2). The method was used to observe the influence of the insecticide imidacloprid on feeding activity in a chronic exposure test (exp.3).
In the present study, the impacts of parasite infection as well as the influence of food quality separately were significant. Parasite infection and lower food quality together yield an even stronger reduction of the feeding rate of Gammarus pulex in relation to uninfected and optimally-fed organisms. In terms of size dependence of the feeding rate, the results of this experiment agreed with those in the literature. Furthermore it could be demonstrated that daily measurement of feeding activity on an individual level was feasible, but there were some unidentified factors which reduced the feeding rate over time.
The observed effect concentration for imidacloprid for an exposure duration of four days was 20 to 380 times lower than the lethal concentration. Furthermore, the effect concentrations were within the range of measured and estimated environmental concentrations.
Intra-specific variability makes it difficult to study sub-lethal effects on an individual level and experimental design should minimise variability wherever possible. It is known that lethal and sub-lethal impacts can still be seen after the toxicant is removed from the exposure medium. In this experiment, a secondary effect (higher feeding rate in previously impacted individuals) also persisted beyond the time when the toxicant was eliminated from the water phase. It is essential that experimental duration should be sufficient to study such compensatory effects.

**ET04-3**

**Non-guideline studies refine and improve the aquatic risk assessment of forest insecticides imidacloprid and neem**

DP Kreutzweiser, DG Thompson
Canadian Forest Service, SAULT STE MARIE, Canada

Most pesticide risk assessment frameworks include a problem formulation phase in which relevant measurement and assessment endpoints are identified. Functional attributes or measurement endpoints are not typically used in risk assessments under FIFRA (USA) or the PCPA (Canada) because it is generally accepted that protection of structural endpoints will protect ecosystem function. However, we provide two examples where non-guideline laboratory and outdoor mesocosm studies detected significant alterations to population and community functional attributes at realistic concentrations that would not likely have been predicted from standard or tiered toxicity testing. These studies were conducted in the context of synthetic (imidacloprid) and natural (neem) forest insecticides. Realistic aqueous concentrations of neem (azadirachtin) in outdoor mesocosms selectively reduced a key group of macro-crustaceans and the resulting zooplankton community alterations were sufficient to induce measurable changes in whole ecosystem metabolism. Realistic foliar concentrations from systemic applications of imidacloprid in laboratory mesocosm studies significantly reduced organic matter decomposition rates through sub-lethal feeding inhibition effects on obligate leaf-shredding aquatic insects. No such effects were detected for realistic foliar concentrations of neem (azadirachtin). We show how hypotheses generated by combining known ecological, use pattern, and exposure scenario information were used to direct adaptive, non-guideline studies for assessing risk to aquatic communities. These non-guideline studies can provide ecologically-relevant ancillary data for regulatory guideline data submissions to increase environmental realism, reduce uncertainties, and improve an overall risk assessment for forest insecticides.

**ET04-4**

**Effects and environmental consequences of U exposure on the fish Danio rerio**

O Simon, E Floc'H, B Geffroy, R Gilbin
IRSN, SAINT PAUL LEZ DURANCE, France

Exposure to metals can cause a decrease of reproductive capacity in fish. These endpoints may have serious implications for normal population dynamics and community structures. Uranium's environmental prominence is currently increasing because of new mining and milling activities ([U] in water: 200-3000 µg.L-1). Hence, the objectives were to measure the effects of U in egg (survival rate) and adult stages (reproduction output, fertilization, fecundity) of the fish Danio rerio after short and long exposure duration and to quantify the impact on live-history traits of fish. They could allow to develop/valid toxicity tests more accurate for the environmental risk assessment.
No mortality in eggs and no disruption of the main embryo development stages were observed after direct 96h-U exposure. However, eggs were significantly affected by the U exposure; effects of U on hatching success starting at the concentration of 300 µg.L-1 causing a delay in hatching time.
Effects on the adults, 20d of exposure reduced the number of egg spawned (x5) although no egg was spawned after the 200d of exposure. For the 20 µg.L-1 exposure, the number of eggs was reduced by 3-2.5. Moreover, the viability of eggs was reduced (21%) after 200d. In the case of whole life cycle experiment, sex ratio, fecundity, viability and the ability to spawn were widely modified by U exposure. The sensibility of adult U response was widely influenced by the age at the beginning of the exposure modalities.
A simple population model included these endpoints were used to evaluate the U effects. Dynamic of population was altered by uranium exposure. As expected, the most representative test (long term of exposure/whole live cycle) will provide better information on the environmental risk of U exposure.

**ET04-5**

**Impact of pesticides in small streams in central Germany - Effect of pesticides on macroinvertebrate drift, emergence and feeding rates of Gammarus pulex**

K Maaβen[1], C Janoske[2], R Ohliger[2], R Schulz[2]
[1]DR. KNOELL CONSULT GmbH, MANNHEIM, Germany
[2]University Koblenz-Landau, LANDAU, Germany

The influence of pesticides on aquatic stream communities was investigated in an intensively used agricultural landscape in central Germany. Pesticide exposure was examined at 10 sampling sites at a total of seven streams using event controlled runoff sampling systems and suspended particle samplers (SP samplers). Samples were taken following heavy rainfall events and analyzed for 14 pesticides. In order to identify the risk to aquatic communities, the macroinvertebrate drift (drift net; n=1), insect emergence (emergence tents; n=4) and feeding rates of *Gammarus pulex* in in situ bioassays (n=20) were assessed at each sampling site.
The water samples of two streams as well as most SP samples contained insecticides at ecotoxicological relevant concentrations. The macroinvertebrate drift of *Gammarus pulex* and *Limnephilus lunatus* was high following a rainfall-induced input of the insecticide lambda-cyhalothrin (0.29 µg/L) at one sampling site. The feeding rate of *Gammarus pulex* was also reduced following this rainfall event. Moreover at a further study site, the insecticide lambda-cyhalothrin (SP: 53.2 µg/kg) was found to be responsible for an increase of the macroinvertebrate drift rate.
Significantly reduced feeding rates in in situ bioassays were identified at two sites ($p = 0.01$ and $p = 0.006$, respectively), which correlated with an input of insecticides to both streams. The influence of physico-chemical parameters (pH, conductivity, water temperature and oxygen content) on the feeding rate was excluded through the use of correlation analysis. No effect of the pesticides on the insect emergence rates was visible since other factors had greater impact (short examination period, difference in appearance of species during the season, temperature).
The observed reduced feeding rates of *Gammarus pulex* in in situ bioassays and the increased drift rates show the impact of pesticides on small streams. The amphipod *Gammarus pulex* plays an important role within stream ecosystems as a detrivore, and the disturbance of this species can have significant effects upon both the invertebrate communities and the stream ecosystem as a whole. Appropriate risk management measures can minimize the observed effects of pesticides. Furthermore positive effects to the aquatic communities are expected from improvements of in-stream structures.

**ET04-6**

KEYBIOEFFECTS was a Marie Curie Research Training Network (RTN) aiming to gain a deeper understanding of the anthropogenic toxic compounds released in European water bodies. While environmental risk assessment is commonly based on Priority Pollutants (PPs) data and toxicity results obtained from standardized toxicity tests, Keybioeffects research was focused on several knowledge gaps: identification, toxicity, fate and monitoring of emerging compounds and transformation products; bioavailability, trophic transfer, direct and indirect effects of chemicals on natural populations and communities and the evaluation of the environmental effects of chemical pollution in several European river ecosystems.
In this presentation, the main research findings will be summarized and a few examples presented in detail to illustrate our research output and open questions. Overall, the results obtained demonstrate that chemical pollution, including priority and emerging compounds as well as non-identified toxic compounds, is posing a risk to the ecological integrity of European rivers. Furthermore, sampling strategies, experimental approaches, analytical and bio-analytical methods applied or developed within the network are recommended as innovative and sensitive tools to better address the environmental risk of pollutants and identify the causes of ecological deterioration as the European Water Framework Directive requires.

## ET05 - Ecosystem exposure, toxicity pathways and adverse health outcomes

**ET05-1**

**Effects of ingestion of fungicide- and insecticide-coated seeds on red-legged partridge (Alectoris rufa) health**

ME Ortiz-Santaliestra[1], A López-Antia[1], F Mougeot[2], R Mateo[1]

[1]Instituto de Investigación en Recursos Cinegéticos CSIC-UCLM-JCCM, CIUDAD REAL, Spain
[2]Estación Experimental de Zonas Áridas CSIC, ALMERÍA, Spain
Pesticide application is suspected to be a major cause of population decline in farmland birds. Seeds coated wit fungicides or insecticides constitute a main part of the diet of species such as the red-legged partridge (*Alectoris rufa*) during sowing seasons. The aim of this study was to test the effects of coated seed ingestion on *A. rufa* physiology and general fitness. We tested an insecticide (imidacloprid) and two fungicides (difenoconazole and thiram). Each experiment consisted in two groups of six pairs of partridges each: the low dose consisted in seeds treated with the recommended dose and the high dose in seeds treated with a concentration twice the recommended one. A third group was fed with untreated seeds and used as control. Seeds administration was prolonged for a 10-day period, after which all animals were transferred to an untreated diet and monitored for an additional 12 days. Right after the exposure and after the monitoring periods we took body mass, ventilation rate, beak and eye ring pigmentation, hematocrit, plasma testosterone and estradiol levels, vitamin and carotenoid profiles and oxidative stress parameters (TBARs, GPx, SOD and GSSG/GSH ratio). Immunocompetence was analysed at the end of the experiment by testing cellular (PHA test) and humoral (SRBC-agglutination test) responses. High concentrations of imidacloprid and thiram caused 58% and 42% mortality, respectively, whereas >80% of controls survived. Sex-dependent lethal effects were detected for thiram, being males more affected than females. Low concentrations induced significant weight loss, although survivors recover quickly once the exposure was terminated. These low concentrations also induced oxidative stress. SOD was significantly stimulated by thiram ($F_{2,28}$=7.539; $p$=0.002), whereas imidacloprid induced the activity of GPx ($F_{2,22}$=6.651; $p$=0.006). Imidacloprid was the only immunosuppressive pesticide, impairing the cellular immune response ($F_{2,25}$=4.809; $p$=0.017). Beak redness was reduced by the low imidacloprid concentration, although this effect was statistically significant only for females ($F_{2,14}$=4.036; $p$=0.041). The two fungicides also affected ornamentation by reducing the percentage of eye ring pigmentation (thiram: $F_{2,32}$=6.158; $p$=0.005. difenoconazole: $F_{2,32}$=4.245; $p$=0.023). Coated seed consumption may compromise health of farmland birds, especially during seasons when little alternative food sources are available in the field

### ET05-2

**Ecosystem exposure and adverse human health effects of POPs: a data analysis approach by a discrete mathematical method**

K Voigt[1], R Bruggemann[2], KW Schramm[1]
[1]Helmholtz Zentrum Muenchen, NEUHERBERG, Germany
[2]Leibniz-Institute of Fresh Water Ecology and Inland Fisheries, BERLIN, Germany
It has been evident for decades that environmental chemicals pose an enormous risk to the environment as well as to humans. However, this important topic is still underestimated in every part of society. The effects of environmental contaminants on health are a major concern because exposure is associated with the alteration of human sex ratio, as well as with a number of diseases, including cancer, diabetes, congenital malformations and infertility, etc.
It is clear that there is increasing pressure to intensify the research and to more efficiently evaluate the data on persistent and bioaccumulative chemicals in the environment as well as in human bodies.
In our data-analysis approach we investigated data sets of breast milk samples of women in Denmark and Finland which contained measurable levels of 32 Persistent Organic Pollutants (POPs). In each country the breast milk of 65 women was analysed. Therefore we have to evaluate a data matrix with 32 rows (the chemicals) and 65 columns (the breast milk samples of 65 anonymous women). Out of the 65 samples (complete data matrix) in each country we selected two different subsets according to healthy boys and boys with cryptorchidism, a malformation of the testis. Furthermore, we investigate if and how the physical-chemical properties logPow and BCF are associated with the contamination of human breast milk samples in 32 selected POPs.
The data-analysis method is based on the theory partially ordered sets. The theory of partial order is a discipline of Discrete Mathematics. An overview can be found in a book edited by the second author. The graphical representation of partial orders is laid down in so-called Hasse diagrams. The software package applied is named PyHasse, written by the second author. This software package is still under development. However, it can be obtained by the second author.
In the Hasse diagram technique the ordering of the chemicals, their different positions in the Hasse diagrams and the quantification using partial order theoretical method are, however, new and important amendments in the findings of chemicals influencing the state of health of human beings. The comparisons (similarity analysis) of data sets of Danish and Finnish breast milk samples (healthy, cryptorchidism) with logPow/BCF of the 32 chemicals reveals similar structures of the diagrams. It shows that the physical chemical properties logPow and BCF are good indicators for the ranking of the used POPs.

### ET05-3

**Transcriptomic and enzymatic approaches on the freshwater fish Gobio gobio exposed to two PCBs**

P Doyen[1], L l'Hoste[1], L Hoffmann[1], F Rodius[2], HM Cauchie[1]
[1]Centre de Recherche Public - Gabriel Lippmann, BELVAUX, Luxembourg
[2]Université Paul Verlaine - Metz, METZ, France
The production of polychlorinated biphenyls (PCBs) is forbidden since the 1980's but, due to their high stability in the environment, these molecules are nowadays ubiquitously distributed in freshwater and more particularly in sediments. Moreover, PCBs have the capacity to biomagnify in the aquatic trophic webs. The use of transcriptomic in ecotoxicology allows to observe the effects of PCBs at cellular and molecular levels. This can provide some early predictive indicators of these pollutant effects. Some fish species are commonly used in ecotoxicological studies at transcriptomic level but few are fishes living close to the sediments. The gudgeon Gobio gobio is a benthopelagic freshwater fish, common in European rivers, which is exposed to the pollutants contained in rivers water and sediments.
The purpose of this study was to evaluate the effect of two PCBs on the mRNA expression and the enzymatic activities of gudgeon detoxification systems.
In first step, the gudgeon coding sequences of cytochromes P450 (CYP) 1A, pi-class glutathione S-transferase (pi-GST), selenium-dependent glutathione peroxidase (Se-GPx) and catalase (CAT) have been identified.
In a second step, gudgeons were exposed to a non-dioxin PCB (PCB 153), to a dioxin-like PCB (PCB 77) and to a mixture of both PCBs. Exposures were performed using food containing four PCB doses (10 ng/g, 100 ng/g, 1 µg/g and 10 µg/g) for 1, 3, 7 and 14 days. The expressions of the four detoxification genes have been studied by real-time PCR in the liver of gudgeons.
The PCB 153 had no effect on CYP1A, pi-GST, Se-GPx and CAT expressions whereas the PCB 77 or the mixture of the two PCBs led to expression variations. For example, an induction of CYP1A expression was observed from the first day of exposure with 1 µg/g of PCB 77.
The measurement of the activities of these detoxification enzymes is ongoing in order to compare the responses at the transcriptional and the enzymatic levels.
This study provides the first data about detoxification responses at both transcriptional and enzymatic levels in the liver of Gobio gobio. These parameters could be used as potential biomarkers for pollutants monitoring.

### ET05-4

**Specific gene responses of exposure to acetylcholineesterase inhibitors are mediated via nicotinergic acetylchline receptors and elevated intracellular calcium levels**

N Klüver[1], L Yang[2], W Busch[1], K Scheffler[1], P Renner[1], U Strähle[2], S Scholz[1]
[1]Helmholtz Centre for Environmental Research - UFZ, LEIPZIG, Germany
[2]Karlsruhe Institute of Technology (KIT), Institute of Toxicology and Genetics, KARLSRUHE, Germany
The identification of chemical-specific gene expression patterns can be used to assign mode of actions to non-characterised or unknown chemicals. In order to exemplarily demonstrate that specific expression patterns can also be obtained for compounds that do not directly interfere with transcriptional regulation, we analysed the effects of the neurotoxic acetylcholinesterase inhibitor azinphos-methyl (APM). Zebrafish embryos exposed for 24 and 48 hours were used as a model. Hierarchical cluster analysis of microarray data and comparison with two non-AChE inhibiting control compounds (1,4-dimethoxybenzene, 2,4-dinitrophenol) revealed a highly specific cluster of APM induced genes. Subsequent detailed analysis of one of the most strongly induced genes, hspb11, indicated that changes in expression were mediated via the nicotinergic acetylcholine receptor (nAChR) and increased Ca2+ levels. For instance, the expression patterns were compliant to those observed for various mutant strains. Furthermore, modulators of intracellular calcium levels such as thapsigargin and caffeine induced hspb11. The data demonstrated the strength of combining transcriptome and functional analyses in the zebrafish embryos to assign gene expression changes to a specific mode of action.

### ET05-5

**Proteome profiling reveals potential toxicity and detoxification pathways following exposure of BEAS-2B cells to engineered nanoparticle titanium dioxide**

Y Ge[1], M Bruno[2], K Wallace[2], W Winnik[2], P Raju[2]
[1]US Environmental Protection Agency, DURHAM, United States of America
[2]US EPA, DURHAM, United States of America
Identification of toxicity pathways linked to chemical exposure is critical for a better understanding of biological effects of the exposure, toxic mechanisms, and for enhancement of the prediction of chemical toxicity and adverse health outcomes. To identify toxicity pathways and networks that are associated with exposure to engineered nanomaterials, an integrated proteomic study was conducted using human bronchial epithelial cells, BEAS-2B and nanoscale titanium dioxide. Utilizing two-dimensional gel electrophoresis (2-DE) and mass spectrometry (MS), we identified 46 proteins that were altered at protein expression levels. The protein changes detected by 2-DE/MS were verified by functional protein assays. The identified proteins include some key proteins involved in cellular stress response, metabolism, adhesion, cytoskeletal dynamics, cell growth, cell death, and cell signaling. These differentially expressed proteins were also mapped to identify potential toxicity pathways of titanium dioxide using Ingenuity Pathways AnalysisTM (IPA). Twenty protein canonical pathways and tox lists were generated from the analysis, and these pathways were compared to signaling pathways generated from genomic analyses of BEAS-2B cells treated with titanium dioxide. There was a significant overlap in the specific pathways and lists generated from the proteomic and the genomic data. In addition, we also analyzed the phosphorylation profiles of protein kinases in titanium dioxide-treated BEAS-2B cells for a better understanding of upstream signaling pathways in response to the titanium dioxide treatment and the induced oxidative stress. In summary, the present study provides the first protein interacting network maps and novel insights into the biological responses and potential toxicity and detoxification pathways of titanium dioxide.

### ET05-6

**Modulation of immune parameters by chemical environmental pressures in wild populations of European bullhead, Cottus sp. from Vesle Basin (Champagne, France)**

A Bado-Nilles[1], S Jolly[2], A Geffard[1], B Gagnaire[3], N Cadic[4], JM Porcher[2], W Sanchez[2], S Betoulle[1]
[1]University of Reims Champagne-Ardenne, REIMS, France
[2]Ineris, VERNEUIL-EN-HALATTE, France
[3]IRSN, SAINT-PAUL LEZ DURANCE, France
[4]ONEMA, MARLY, France
In freshwater ecosystems, a large number of chemical substances are able to disturb homeostasis and adaptative responses of fish organisms by modulating different physiological functions including immune system. In order to characterize the early biological effects of environmental contaminants on fish health status, some immune-related cellular and biochemical responses were proposed as immunotoxicological biomarkers. The aim of the present study was to evaluate immune status of European bullhead, Cottus sp., natural populations, living in different field contexts characterized by various chemical environmental pressures. In Champagne region (France), five sites of the Vesle watershed in the North East of France were selected with urban (Muizon), intensive agricultural (Bouy and Prunay) or viticultural (Serzy and Prunay) influences. For each location, adult fish were caught by electrofishing in spring, summer and autumn and splenic leucocyte parameters (leucocyte sub populations, cell mortality and phagocytosis) were carried out by flow cytometry. Fish biometric characteristics, such as length and weight, have no impact on immune parameters. Seasonal variations in immune responses depended on the tested immune function without discrepancy between studied sites. For example, the lymphocyte percentages were higher in summer whereas leucocyte mortalities were strongly increased in spring and phagocytosis percentages in autumn. Nevertheless, independently of seasonal variations, environmental characteristics of each site seem to disturb selected immune markers. The highest immune modulations were observed in sites situated in areas with intensive agriculture or viticulture, Bouy, Prunay and Serzy respectively. These first results may indicate possible immunotoxicological impacts of agri-viticultural practices on bullhead natural populations living in Vesle watershed. It is sure that further observations, on many years, have to be done to verify observed immunomodulations. Moreover, data are needed to better characterize the effects of biotic and abiotic confounding factors on these biomarker base levels and to define their natural variability ranges for assessment of wild fish health.

## ET06 - Ecotoxicology of amphibians and reptiles

**ET06-1**

**Multi-endpoint assessment of the effects of chlorpyrifos ingestion in a lacertid lizard (Podarcis bocagei)**

A Amaral[1], RC Bicho[1], MA Carretero[2], JC Sanchez-Hernandez[3], R Valente[1], AMR Faustino[4], AMVM Soares[1], RM Mann[5]
[1]CESAM & Universidade de Aveiro, AVEIRO, Portugal
[2]CIBIO, Centro de Investigação em Biodiversidade e Recursos Genéticos, VAIRÃO, Portugal
[3]Facultad de Ciencias del Medio Ambiente, Universidad de Castilla-La Mancha, TOLEDO, Spain
[4]Departamento de Patologia e Imunologia Molecular, ICBAS, Universidade do Porto, PORTO, Portugal
[5]Hydrobiology, QUEENSLAND, Australia

Lizards are among the least studied groups in ecotoxicology, and despite a recent increase in the number of studies, there is still a lack of knowledge regarding their response to environmental contamination. In Europe, lacertid lizards have been identified as potential model species for reptile ecotoxicology. Chlorpyrifos is one of the main organophosphorus insecticides used in agricultural areas and has been reported as moderately toxic and a cholinesterase inhibitor. Adult male *Podarcis bocagei* (n=36) were captured in a non-contaminated site and exposed under controlled conditions to a commercial formulation of chlorpyrifos (CICLONE 48 EC - 480 g/L, SAPEC AGRO). Individuals were assigned to three treatments: control (dH2O), CPF1 (96 ng cpf/meal) and CPF2 (960 ng cpf/meal). The CPF was injected into live mealworms, which were provided as meals every second day over a 20-day period. After 20 days feeding, 18 individuals (6 per treatment) were fasted and subjected to individual performance tests and the remaining were sacrificed and dissected for biochemical assays, histopathological analysis in liver and testes and hemoparasite prevalence/intensity. There were no significant differences regarding running speed between treatments. In the predatory behavior experiment there was a tendency for exposed animals to take more time to subdue and swallow the prey. There were no statistical differences in the proportion of lizards with hemoparasites. Exposition to chlorpyrifos did not produce any variation in stress oxidative enzymes regarding the control group in any of the studied tissues. Esterase activity was significantly inhibited by chlorpyrifos with CbEs having a higher sensitivity than AChE. In general, no histopathological changes were observed in livers of treated animals, although CPF2 exposed individuals presented higher levels of congestion. Seminiferous tubule diameter was not different and all spermatogenic stages were present in control and treated individuals. A tendency for larger lumen was observed in treated individuals. When exposed to environmentally relevant doses of chlorpyrifos *P. bocagei* displayed carboxylesterase and acetylcholinesterase inhibition in all tissues examined. These biomarkers of exposure were accompanied by behavioral symptoms of neurotoxicosis, including reduced capacity to respond to prey cues. The implication of these studies is that environmental exposure to chlorpyrifos may affect individual fitness.

**ET06-2**

**Effects of field-exposure to agricultural pesticides on thyroid and on testis in the lizard, Podarcis bocagei: A histopathological study**

CSS Bicho[1], MJ Amaral[1], AMR Faustino[2], RV Duarte[1], A Rêma[2], MA Carretero[3], AMVM Soares[1], RM Mann[4]
[1]Universidade de Aveiro, AVEIRO, Portugal
[2]Universidade do Porto, PORTO, Portugal
[3]Centro de Investigação em Biodiversidade e Recursos Genéticos, VAIRÃO, Portugal
[4]Hydrobiology, QUEENSLAND, Australia

The use of pesticides in agriculture is a source of environmental pollution in these environments. Many wildlife species use agriculture fields as habitat and are routinely exposed to these chemicals. Lacertid lizards are an important group of reptiles occupying agricultural landscapes in Europe that have been identified as potential model species for reptile ecotoxicology; however, little is known about the effects of pesticides on these animals. Many pesticides can have endocrine effects observable within organs associated with reproduction, growth and development (e.g. gonads, thyroid). The aim of this study was to evaluate the effects of field-exposure to pesticides on the thyroid gland and on testis function. Adult male lizards were captured in north-western of Portugal, within corn fields treated with pesticides and from agriculture fields designated for biological agriculture and which therefore did not use pesticides. All animals were collected during autumn of 2009. Animals were sacrificed and thyroids and testis were removed for histological analysis. Thyroid histology indicated that exposed animals displayed follicular lumens with more reabsorption vacuoles and a significant difference in follicular area (when compared to thyroids taken from reference animals) On the other hand testis histology indicated that testicular diameters among exposed animals were significantly larger in exposed animals compared to testes taken from reference animals. These results suggest that the complex mixture of pesticides that animals were being exposed in the field had an effect on thyroid homeostasis and on spermatogenesis and may indicate that one or a combination of pesticides are acting as endocrine disruptors among these populations of P. bocagei.

**ET06-3**

**Effects of Roundup® on the protein expression patterns in the liver and brain of metamorphosing common frog Rana temporaria**

CM Gillardin, F Silvestre, A Oriol, M Dieu, M Raes, P Kestemont
Facultés Universitaires Notre-Dame de la Paix, NAMUR, Belgium

The worldwide decline of amphibian populations, reported in a large variety of habitats, is often linked to destruction, disturbance, and fragmentation of the habitat. But the environmental presence of chemical compounds such as pesticides has been considered as a possible factor contributing to the reported decline. One of the widely used herbicides is glyphosate which is, among other things, formulated as Roundup®. Up to now, little information is known about the toxicological effects of Roundup® on amphibians. Since the understanding of the mechanisms by which this herbicide may interact with the normal gene expression is of special interest, we evaluated the potential effects of this relevant environmental pollutant on the protein expression in the brain and liver of metamorphosing *Rana temporaria*. To achieve this goal, tadpoles at stage 28 (Gosner index) were exposed to either 1mg or 10µg a.e./L of Roundup® until they reached metamorphosis at stage 44 (Gosner index). For the proteomic analysis, a 2D-DIGE minimal labeling approach coupled to nano flow liquid chromatography tandem mass spectrometry (nano-LC-MS/MS) was applied. When considering the liver, proteins identification suggests that Roundup® may impair mechanisms such as the energetical metabolism (glycerol-3-phosphate dehydrogenase, transaldolase), cellular cycle regulation (60S acidic ribosomal protein P0), hepatic proteolysis (monomeric alpha-macroglobulin), mitochondrial function (carbamoyl-phosphate synthase), and hepatic haem biosynthesis (coproporphyrinogen oxidase). When considering the effects of Roundup® on the brain, results showed that calcium signalling (Annexin A5), neuronal differentiation (Dihydropyrimidase - like3, Dihydropyrimidinase-related protein 5), cellular cycle regulation (Membrane protein-palmitoylated, ndrg2 protein), cytoskeleton (Microtubule-associated protein RP/EB family member 1, Alpha-tropomyosin, Putative actin-capping protein Z beta subunit variant 1, vinculin[3DOTS]), ions transport (ATPase, H+ transporting, lysosomal 70kDa, V1 subunit A 5), and proteins splicing (Splicing factor, arginine/serine-rich 9) were targeted by Roundup®. In conclusion, we can say that our data demonstrate that environmentally relevant exposure to Roundup® can deeply modify amphibian proteome and argue that these changes have to be taken into account while estimating the toxicological hazard of wild amphibian populations exposed to those chemicals.

**ET06-4**

**The role of metabolization processes in micropollutants bioaccumulation by adult green frogs: comparison of benzo[a]pyrene and fipronil toxicokinetics**

IAM Worms, S Reynaud, S Veyrenc, J Portier, M Raveton
Laboratoire d'ECologie Alpine, GRENOBLE, France

The implication of micropollutants (MP) in the global amphibian biodiversity decline is nowadays well accepted. However, there is a paucity of data concerning the biophysico-chemical interactions of MP with adult frogs. The aim of this study is to compare the toxicokinetics of benzo[a]pyrene (BaP) and fipronil (fip), two MP deferring by their origin (combustion vs agriculture) and by their chemical properties ($K_{ow,BaP}$=6 vs $K_{ow,fip}$=2.8 ). Frogs were exposed directly in water for 8 days to low concentration of BaP or fip (10 ppb), containing low quantities of respective radiolabelled molecules. The short-term uptake rates we obtained were equivalent for the two MP. In addition, over the 8 days of exposure, the bioaccumulation factors (BAFs) obtained for fipronil were 2 to 3-time higher than those measured for BaP. These results contradicted with the well accepted consensus for which an increase in $K_{ow}$ led to both an increase in uptake rate and an increase in BAF, and could be the consequence of a better metabolization capability of the frog enterohepatic system for BaP if compared to fip. The results we obtained for MP distribution within the organs, the polarity of the metabolites formed, assessed by thin layer chromatography, as well as the induction of the detoxification enzymes (P450 and GST) in liver (and kidneys) after exposure to BaP or fip comforted this hypothesis. In the light of the findings, potential reproductive dysfunction and embryos development impairment leading to decreased-fitness of amphibian populations are discussed.

**ET06-5**

**Consequences of biofuel crop expansion for amphibian diversity in tropical agroindustrial landscapes**

LC Schiesari[1], BBA Grillitsch[2]
[1]University of Sao Paulo, SAO PAULO, Brazil
[2]University of Veterinary Medicine of Vienna, VIENNA, Austria

The dawn of a new paradigm in energy supply - biofuels - points to the continued expansion of industrial agriculture in the near future. This expansion could have excellent short term economic benefits for tropical countries, but would have to be carefully planned and monitored as industrial agriculture is one of the most important vectors of habitat destruction and degradation worldwide. This study proposes to test the hypothesis that the expansion of soybean and sugarcane, the two most important biofuel crops in Brazil, is associated with significant changes in amphibian community composition, diversity and structure. This hypothesis was tested by means of field surveys in water bodies distributed across a gradient of environmental degradation, i.e., that comprised of native habitats, pastures and plantations, in a soybean-dominated landscape in Southern Amazon and in a sugarcane dominated landscape in southeastern Brazil. Overall, we found a strong signal of land use on amphibian communities both in sugarcane and soybean landscapes, with amphibian community composition in plantations being a subset of that in pastures. Considering that both plantations and pastures are structurally degraded, but that plantations are in addition exposed to a diverse array of agrochemicals, this observation is consistent with a role for environmental contamination in influencing species distributions. The observation of larval amphibian dieoffs in ponds in sugarcane fields, and of strong community level effects in ponds in soybean plantations, both consistent with the timing of application of pesticides, renders further support to this hypothesis. The hypothesis of a link between pesticide contamination and amphibian performance at the individual, population and community level is now being tested by a research program combining further field sampling, and experimentation in laboratory, mesocosm and field.

**ET06-6**

**Atrazine and glyphosate in the environment and its implications for amphibians**

A Bishop[1], V Mcdaniel[1], L Ashpole[2], R Desolla[1]
[1]ENVIRONMENT CANADA, DELTA, Canada
[2]UNIVERSITY OF WATERLOO, WATERLOO, Canada

Herbicides are the top selling pesticides on a global basis. Glyphosate and atrazine are the highest selling herbicides today. Initially registered by Ciba-Geigy in 1958, the triazine herbicide atrazine which inhibits photosynthesis. Monsanto Corp. began to commercially produce glyphosate in 1974. Its mode of action is to disrupt amino acid production in plants. These compounds were registered and their toxicities to organisms have been extensively reviewed without regard for the potential impacts on amphibians or ecosystems in general until recently. The effects of atrazine on amphibians have received wide attention in recent years to the extent that the use of atrazine has been reviewed within the USA based solely on its potential to affect gonadal development in amphibians. The ecosystems and food webs inhabited by herpetofauna may also be altered by atrazine and glyphosate. Our field studies in Canada, indicate that even hatching of amphibian eggs may be affected by atrazine exposure, combined with other pesticides. In the south Okanagan valley, Canada, is a classic location where high biodiversity and human development meet. The intensive use of pesticides combined with loss of habitat and degradation of habitat due to other factors led our team to counter by creating new habitats for amphibians with conservation covenants in the hope that this will preserve the many species at risk that depend on water in this desert region.

## ET07 - Endocrine disrupting chemicals in the environment

**ET07A-1**

**Freshwater mudsnail estrogen receptor - identification and regulation**

D Stange
Goethe University Frankfurt am Main, FRANKFURT, Germany

Molluscs are raising attention as ecotoxicological test organisms due to their high diversity and importance in aquatic ecosystems. The ovoviviparous prosobranch gastropod *Potamopyrgus*

*antipodarum* (freshwater mudsnail) responds very sensitively to xenobiotics and has therefore been proposed as OECD standard test organism. Endocrine disrupting chemicals influence the reproduction of *P. antipodarum* which can be assessed by embryo numbers in the broodpouch. However, the knowledge about the endocrine system of *P. antipodarum* is rather limited. The aim of this study is to identify an estrogen receptor in the endocrine system of *P. antipodarum* and to investigate if this receptor is differentially expressed under different (xeno-)hormone exposures (i.e. 17α-ethinylestradiol, bisphenol A and 17α-methyltestosterone).
The DNA-binding domain of the identified ER-like transcript has an amino acid identity of 92% compared to the ER of the gastropod *Nucella lapillus* (84% to human ERα) and 83% in the ligand-binding domain (38% to human ERα). Furthermore, the *Potamopyrgus*-ER is transcriptionally regulated as proofed by quantitative Real-Time PCRs of (xeno-) hormone exposed snails.

**ET07A-2**

**Quantification of vitellogenin by mass spectrometry (LC-MS/MS) in the freshwater amphipod, Gammarus fossarum : a potential endocrine disruption biomarker**

G Jubeaux[1], R Simon[2], F Audouard-Combe[1], H Quéau[1], A Salvador[1], A Chaumot[1], J Garric[1], O Geffard[1]
[1]Cemagref, LYON, France
[2]Université Lyon1, VILLEURBANNE, France

Induction of vitellogenin (Vg) in males or juveniles is a well known effect of xenoestrogenic contaminants in fish, and has been extensively used as a specific endocrine disruption biomarker. Despite their obvious ecological importance, relatively few works have been carried out on invertebrates and consequently few tools are available to diagnose an endocrine disruptor exposure in these species. At present, only indirect methods, such as the organic alkali-labile phosphate (APL) assay, have been proposed and applied in invertebrates species. From an analytical point of view, efforts should also be directed toward developing more specific methods to measure Vg levels in invertebrates.
This study focuses on the development of a new Vg quantitative assay in an ecologically relevant freshwater invertebrate, Gammarus fossarum, using liquid chromatography tandem mass spectrometry (LC-MS/MS). For this end, we followed an approach in three steps, i) we developed a quantitative SRM (Single Reaction Monitoring) assay for the detection of proteotypic Vg peptide, ii) the specificity of this proteotypic peptide as indicator of the functional Vg was validated, by assessing its natural variability during the reproductive cycle of female organisms and iii) the use of this approach as biomarker was evaluated, by studying the modulation of the proteotypic peptide in gammarids exposed to known endocrine disruptors. From this study, an analytical method allowing an absolute quantification of vitellogenin in G. fossarum was developed. The use of this assay as a specific endocrine disruption biomarker was validated by assessing the modulation of vitellogenin levels in gammarids females exposed to the 20-hydroxyecdysone and the methyl-farnesoate.

**ET07A-3**

**H295R cells as a steroidogenic model: a broader picture using simultaneous chemical analysis of 7 key steroid hormones exposed to 3 endocrine disruptors**

FK Nielsen, CH Hansen, JA Fey, M Hansen, NW Jacobsen, E Björklund, B Styrishave
University of Copenhagen, COPENHAGEN, Denmark

Much effort has focused on substances interfering with hormone function, and more recently research on substances that interfere with the natural production of hormones has developed. Important work in this field is the validation of the H295R cell line as a steroidogenic model [1].
In the present study prochloraz, ketoconazole and genistein were tested as previous studies have given inputs to understanding where in the steroidogenic pathway they interfere. However, by applying simultaneous chemical analysis of 7 key steroid hormones in the pathway, a better understanding of the rate limiting steps can be achieved. Furthermore this method negates the problems of cross-reactivity encountered in immunoassays.
The H295R steroid hormone synthesis assay (http://www.oecd.org/dataoecd/56/11/44285292.pdf) was performed (with minor modifications) and analyzed according to a simplified version of the method described by Hansen et al [2]. In short 3 pooled wells of cell medium was added internal standards and concentrated on C18 solid phase extraction cartridges. Steroids were then derivatized with TMS and analyzed using GC-MS-MS.
Although all 3 test compounds also leads to decreases in testosterone and 17beta-estradiol as previously described in the literature, effects are observed on all other analyzed steroids (pregnenolone, progesterone, dehydroepiandrosterone, androstenedione and estrone). This study also demonstrate that the steroidogenic pathway is disturbed at different stages by the 3 test compounds. Applying the analytical method used in this study to measure hormone production in the H295R cell line offers significant advantages compared to immunoassays.

- Accurate simultaneous hormone baseline measurements of seven key hormones (pregnenolone, progesterone, dehydroepiandrosterone, androstenedione, estrone, testosterone and 17beta-estradiol)
- No cross reactivity
- Differentiation of where the steroidogenic pathway is affected by test compounds

**Evidence of feminization in wild Elliptio complanata mussels in the receiving waters downstream of a municipal effluent outfall**

F Gagné[1], BB Bouchard[2], CA André[1], EF Farcy[2], MF Fournier[2]
[1]Environment Canada, MONTRÉAL, Canada
[2]INRS-Institut Armand Frappier, LAVAL, Canada

The endocrine-disrupting activity of municipal effluents has the potential to induce feminization and alter the reproductive systems of aquatic organisms. The purpose of this study was to examine the sex ratio, vitellogenin (Vtg)-like proteins, serotonin, arachidonate cyclooxygenase (COX) activity and dopamine status in wild mussels living at sites upstream and downstream of two municipal effluent outfalls in the Mille-Iles River (Quebec, Canada). Gonad integrity was also studied by monitoring the gonado-somatic index (GSI), the activity of the rate-limiting enzyme aspartate transcarbamoylase (ATC) for purine synthesis, and changes in lipid peroxidation (LPO). The results showed that the proportion of females was dramatically increased from 25-35% at the upstream sites to 80% at the downstream sites. The levels of Vtg-like proteins were significantly elevated in the male mussels only. Male mussels downstream of the municipal effluent plumes expressed female-specific protein bands (Vtg-like), as determined by high-resolution gel electrophoresis and silver staining. The serotonin/dopamine ratio was significantly decreased in the downstream mussels, indicating that the gonad was in a state of early vitellogenesis. However, this change was not accompanied by changes in ATC, suggesting no significant egg production; this was confirmed by the observation that the downstream mussels displayed significantly low GSIs. Indeed, GSIs were rather dependent on the serotonin/dopamine ratio ($r=0.44$; $p<0.001$), while Vtg-like proteins were dependent on dopamine levels ($r=0.5$; $p<0.001$). The increase in COX activity at the downstream sites and its close relationship with increased serotonin levels suggest a concomitant serotonergic signalling in addition to VTG production. The production of Vtg-like proteins combined with the serotonergic effects of the municipal effluents was associated with oxidative damage (LPO) in the gonad. This study provides the first evidence of feminization in wild mussel populations and the disruption in gonad physiology by exposure to municipal effluents.

**ET07A-5**

**Effect directed analysis of estrogenic effects in sediments of the river Elbe**

S Buchinger, S Schmitt, E Claus, M Schlüsener, G Reifferscheid
Federal Institute of Hydrology, KOBLENZ, Germany

The aim of the present study was, to comprehensively identify substances that are responsible for the estrogenic effect of an environmental sediment sample taken from the river Elbe / Germany. The estrogenic effect of the organic sediment extracts was determined using the Yeast-Estrogen-Screen (YES). The sample was fractionated by liquid chromatography for effect directed analysis. The composition of estrogen-active fractions was further investigated by GC-MS and high resolution LC-MS analysis. Identified substances were tested in the YES and additive effects of the mixture were calculated using the concept of concentration addition (CA). The composition of the environmental sample was rebuilt with pure compounds based on the data of the chemical analysis in order to assess the partition of estrogenic activity caused by the identified compounds. The organic sediment extract showed an estrogenic potential of 1,9 ± 0,4 ng/g ethinyl-estradiol-equivalents (EEEQ) in the sediment. We were able to identify 13 substances by effect directed analysis of which eight had xenoestrogenic properties. The most prominent were 17-beta-estradiole and estrone, but alkylphenols, bisphenol-A and stigmasterol could be found as well. Chlorophene (o-benzyl-p-chlorophenol) - a widely used antiseptic that was also identified in the sediment extract - has xenoestrogenic properties in the YES that are in the range of other xenoestrogens like 4-n-Nonylphenol. This is the first report on chlorophene acting as a xenoestrogen. Furthermore, the estrogenic potentials of mixtures comprising of both, xenoestrogens and non-active substances were analyzed. The results indicate a substance-specific modulation of the estrogenic effect by compounds that are present in the analyzed sample and do not stimulate the human estrogen receptor by themselves. As one example the non-active compound tocopherol enhanced in a concentration dependent matter the estrogenic potential of the technical mixture of nonylphenols whereas the potential of bisphenol-A was unaffected. This finding indicates the importance of mixture effects and underlines the need for bio-assays for the integrative analysis of environmental samples.

**ET07A-6**

**In vitro bioassays to monitor estrogenic activity of surface and drinking waters in Brazil**

AMDD Bergamasco[1], ME Eldridge[2], FF Sodré[3], P Montagner[4], I Pescara[4], WF Jardim[4], GA Umbuzeiro[4]
[1]University of São Paulo - USP, SÃO PAULO - SP, Brazil
[2]University of Tennessee, KNOXVILE, United States of America
[3]University of Brasília, BRASÍLIA, Brazil
[4]University of Campinas UNICAMP, CAMPINAS, Brazil

Estrogenic Endocrine Disrupting Chemicals (EDCs) are compounds able to cause adverse effects to humans and wildlife, and have frequently been detected in the environment. Increasing efforts from governmental sectors and the scientific community are devoted to the development of methods to quantify these compounds and predict the risks they pose to humans. The aim of this work was to evaluate selected EDCs of raw and treated waters in Brazil with different levels of pollution, using chromatography-tandem mass spectrometry (LC-MS-MS) and verify their potential biological effects via in vitro yeast bioassays. Two different bioluminescent yeasts containing the human estrogen receptor were employed. One of the strains contains the *luc* from a firefly and the other the *lux* genes from bacterias (BLYES) as reporters of the estrogenic activity. All raw waters presented endogenous and/or xenoestrogens and showed estrogenic activity in at least one sampling. Estrogenic compounds and estrogenic activity were not detected in treated waters. All samples containing estrogenic compounds presented estrogenic activity in the BLYES method but not in the luc gene based method. In general, the concentrations of target-compounds determined by chemical analysis did not explain the biological responses observed. Because of its simplicity, low cost and good sensitivity, the biological approach showed to be appropriate for monitoring raw and drinking water, indicating hot spots events to be further chemically characterized.

**ET07B-1**

**Triclosan does not alter secondary sexual development or steroidogenesis in juvenile silurana tropicalis**

S Pawlowski[1], J Fort[2], L Rogers[3], S Unger[4], R Peter[5]
[1]BASF SE, LUDWIGSHAFEN, Germany
[2]Fort Environmental Labs., STILLWATER, United States of America
[3]Fort Environmental Labs, STILLWATER, United States of America
[4]BASF Schweiz AG, BASEL, Switzerland
[5]Intertek Expert Services, BASEL, Switzerland

The impact of the anti-bacterial agent, triclosan (Irgasan® or TCS), on gonadal steroidogenesis during sexual differentiation in Silurana tropicalis was examined. In previous studies, TCS did not alter the normal course of thyroid-mediated metamorphosis in Xenopus laevis, or alter reproductive fecundity or endocrine status in adult fathead minnows (Pimephales promelas) at environmentally relevant concentrations. To evaluate the potential effects of TCS on secondary sexual development and steroidogenesis, a partial lifecycle study initiated with stage 10 embryos and concluding 8 weeks post-metamorphosis was performed using 0.0 (control), 6.3, 12.5, 25, 50 µg TCS/L as target exposure concentrations. Morphological endpoints included visceral development, gonad development, gonad-somatic index (GSI), body weight, and sex ratio. Biochemical endpoints included serum testosterone (T), dihydrotestosterone (DHT), and estradiol (E2); gonadal T; and gonadal CYP 17, CYP 19 (aromatase), and 5α-reductase (5-AR). Exposure to TCS did not alter visceral development, gonad development, GSI, whole body weight, or sex ratios compared to controls. In addition, no significant changes in serum T, E2, and DHT concentrations were found in TCS exposed S. tropicalis compared to controls. Significant changes in gonadal T levels; or CYP 17, CYP 19 (aromatase), or 5-AR activities were not observed in the TCS treatments relative to the controls. Overall, these results demonstrate that TCS does not alter secondary sexual differentiation or steroidogenesis in juvenile S. tropicalis.

**ET07B-2**

**Long-term effects of a binary mixture of perfluorooctane sulfonate (PFOS) and bisphenol A (BPA) in zebrafish**

S Keiter[1], H Färber[2], H Holbech[3], D Skutlarek[2], M Engwall[4], T Braunbeck[1]
[1]Heidelberg University, HEIDELBERG, Germany
[2]Institute for Hygiene and Public Health, University of Bonn, BONN, Germany
[3]Institute of Biology, University of Southern Denmark, ODENSE M, Denmark
[4]MTM Research Centre, Department of Natural Science, Örebro University, ÖREBRO, Sweden

The frequent use of perfluorinated chemicals (PFCs) in industrial applications and domestic products has led on a global basis to a continuous detection of PFCs in a wide range of environmental matrices including aquatic systems. Perfluorooctane sulfonate (PFOS) is the most commonly detected PFC in biotic and abiotic samples. To date, the understanding of the potential effects of PFOS towards biological systems has reached substantial progress. However, the majority of studies have focused on acute effects, leaving long-term effects largely unexplored. Given the persistent properties and the reported membrane altering potential of PFOS a long-term assessment in combination with other pollutants should be a promising strategy to shed more light on the complex toxicology of PFOS. Since PFOS has been shown to act as an endocrine disruptor in fish a combined investigation with another endocrine disrupting chemical (EDC) would represent an approach where specific endpoints such as sex steroid levels could be measured and compared, thus providing a more direct hint of any interactive effects.
In the present study we investigated waterborne PFOS both alone and in a binary mixture with the known EDC bisphenol A (BPA) over two full generations of the zebrafish (Danio rerio). Survival, growth, reproductive success, vitellogenin (VTG) and histological alterations in thyroid, liver and gonads were examined. PFOS (300 µg/L) was found to induce lipid accumulation in liver of F1 generation fish. A parallel finding in PFOS (300 µg/L) exposed fish was the occurrence of granuloma, presumably as a result of bacterial infection. Identical granuloma structures were detected in lower PFOS concentrations in F2 generation fish, indicating a suppressed immune system over generations. BPA tended to increase plasma VTG concentrations whereas the opposite trend was observed for PFOS. Binary mixtures of the two chemicals indicated no synergistic effects. Conclusively our study does not validate the hypothesis that the presence of PFOS increases the endocrine potential of BPA. However, our results indicate an immune suppressing potential of PFOS which seems to be enhanced over generations.

[5]Dept. Biomedical Veterinary Sciences and Tox. Centre, University of Saskatchewan, SASKATOON, SASKATCHEWAN, Canada

Organisms living in aquatic environment are continually exposed to various natural and synthetic compounds that can affect their physiological functions, e.g. modulate the endocrine system, disrupt normal reproduction or developmental processes. Monitoring studies are often focused on assessment of contamination by endocrine-disruptive compounds in abiotic matrices, mainly sediments, surface and waste waters. However, presence of environmental contaminants in abiotic compartments does not indicate necessarily uptake and potential effects on organisms. In this context, use of fish tissue samples for biotests should provide more accurate information about contamination and its reflection in organisms. In two year long study we investigated influence of city agglomeration and large wastewater treatment plant (WWTP) on contamination of river ecosystem by compounds with specific modes of action. The studied area, the second largest city in the Czech Republic (400,000 inhabitants), is spread in the basin of two rivers, with variety of industrial activities and large WWTP. In selected locations sediments were collected in spring and autumn seasons. River water and waste waters from influent and effluent of the WWTP were sampled using two types of passive samplers - semipermeable membrane devices (SPMD) for hydrophobic compounds and polar organic chemical integrative samplers (POCIS) for polar pesticides and pharmaceuticals. In addition to abiotic samples and for better characterization of direct effects on aquatic organisms, the chub (*Leuciscus cephalus* L.) was selected as the most suitable indicator species. Organic extracts of sediments, passive samplers (SPMD, POCIS) and fish bile have been tested by battery of *in vitro* bioassays with recombinant yeast and mammalian cell lines. Specific activities, namely dioxin-like, (anti)estrogenic, (anti)androgenic, and also cytotoxic effects have been determined. Combination of biotests with abiotic and biological matrices enabled complex assessment of contamination by endocrine-disruptive compounds in river ecosystem and possible risks for aquatic organisms. The research has been supported by CETOCOEN (CZ.1.05/2.1.00/01.0001) project granted by the European Union and administered by the Ministry of Education, Youth and Sports of the Czech Republic, and by the projects of the MSMT 2B06093 and ENVISCREEN 2B08036.

**A novel type of endocrine disrupting effect: Octylphenol and 17β-oestradiol cause malformations in eelpout embryos**

P Bjerregaard, RV Nielsen, N Brande-Lavridsen, B Korsgaard
University of Southern Denmark, ODENSE, Denmark

Monitoring programmes (i.e. in Denmark and Germany) have revealed increasing frequencies of malformations among eelpout embryos during recent years. Malformations can be induced in oviparous fish species by exposure to chemicals in the laboratory and the implicit assumption in the eelpout monitoring programmes is that the observed increase in malformations might be caused by changing environmental conditions - including exposure to chemicals. This study aimed at investigating malformations upon exposure of pregnant eelpout to nominal concentrations of 500 ng l-1 17β-estradiol or 100 µg l-1 octylphenol. In the control group, 77.3% of the embryos developed normally, while only 0.9% and 8,8% did so in the groups exposed to 17β-estradiol and OP, respectively. Early death (with or without malformations) and eye and/or spinal cord malformations were observed. Early death dominated in the group exposed to 17β-estradiol and spinal cord deformations dominated in the group exposed to octylphenol. Exposure of pregnant eelpout females to 17β-estradiol and octylphenol at concentrations in the upper range of concentrations found in the environment thus results in abundant malformations among the embryos. This is a novel type of endocrine disrupting effect, and obviously, we want to establish dose-response relationships and no-effect-levels in further investigations. Likewise, we want to elucidate the mechanisms underlying this effect.

**ET07B-5**

**Progress of the Japanese Program on Endocrine Disruption: from ExTEND2005 to EXTEND2010**

K Yamazaki, M Homma, T Hayamizu
Ministry of the Environment, TOKYO, Japan

Ministry of the Environment, Japan launched a new research program on endocrine disruption titled "EXTEND2010"(EXTEND: Extended Tasks on Endocrine Disruption) in July 2010, after reviewing the preceding "ExTEND2005"(ExTEND: Enhanced Tack on Endocrine Disruption). Target of the new five-year program is to accelerate hazard assessment on endocrine disruption of chemical substances, prioritizing organisms in the environment, and to consequently conduct risk assessment to see whether any regulatory risk management measures should be introduced.
As well as promoting research on fundamental science and wildlife observation, test protocols of fish, amphibian and invertebrates have been developed through bilateral or multilateral collaborations. Reliability evaluation of existing knowledge that might be relevant to endocrine disruption is being conducted to select possible candidate chemicals subject to testing to assess their endocrine disrupting effects to aquatic organisms. Framework for assessing endocrine disrupting effects to organisms in the environment is being developed and in vitro tests are conducted for some of the candidate chemicals on a trial basis.
Progress and updated situation of the assessment of chemicals in EXTEND2010 will be demonstrated.

**ET07B-6**

**Effects of endocrine disrupting chemicals on global DNA methylation using in vitro models**

J Legler[1], L Bastos[2], A Boxtel[2], J Kamstra[2], P Cenijn[2], T Hamers[2]
[1]VU University Amsterdam, AMSTERDAM, The Netherlands
[2]VU University, AMSTERDAM, The Netherlands

Epigenetics is an emerging field that has widespread implications for environmental toxicology. By regulating gene expression patterns, epigenetic mechanisms such as DNA methylation are essential in normal development and differentiation. Environmental factors, including contaminants, may alter epigenetic control of gene expression, with important consequences for development and susceptibility to disease. The implications of early life exposure to environmental chemicals on long-term human health via altered epigenetics is a subject of increasing importance. We have recently started a European Commission-funded project called OBELIX ("OBesogenic Endocrine disrupting chemicals (EDCs): LInking prenatal eXposure to the development of obesity later in life"), which tests the hypothesis that prenatal exposure to EDCs plays a role in the development of obesity later in life (see also www.theobelixproject.org). In this project, possible mechanisms of early programming of obesity by EDCs are researched, including effects on DNA methylation. In the study described here, the effects of ten well-known EDCs on global methylation in in vitro models representing two main obesity-related target tissues (hypothalamus and adipose cells) were examined. In addition, the effects of EDCs on differentiation of murine preadipocyte cells were investigated. Results indicate that selected EDCs promote the differentiation of 3T3-L1 cells and cause reduced global DNA methylation. However, no effects of the EDCs were found on global DNA methylation in murine neuronal cells.

## ET08 - Environmental OMICS: a global answer to environmental questions

**ET08A-1**

**A proteomic approach to the development of potential estuarine biomarkers for metal contamination using the Sydney Rock Oyster (Saccostrea glomerata), NSW Australia**

EL Thompson[1], DA Taylor[1], SN Nair[1], G Birch[2], RA Coleman[2], P Haynes[1], DA Raftos[1]
[1]Macquarie University, SYDNEY, Australia
[2]University of Sydney, SYDNEY, Australia

The introduction of waste products into rivers and estuaries in industrial and urbanised areas since the industrial revolution has led to significant increases in chemical contamination. As such, it is now imperative to develop effective monitoring methods to protect biota and the environment. Biomarkers provide information on the cause and effect paradigm of contamination by linking contaminants directly to their effects on biota. However, traditional single parameter biomarker analyses can be insensitive, especially at low contaminant levels. Proteomics provides a new method for identifying potentially hundreds of species specific biomarkers simultaneously at extremely low levels of contamination and over short time periods, allowing early detection of environmental damage.
The current study uses proteomics to assess the effects of metal contamination on Sydney Rock oysters. Saccostrea glomerata were exposed for four days to three environmentally relevant concentrations (100 µg/l, 50 µg/l and 5 µg/l) of copper, lead and zinc. Oyster haemolymph from metal-exposed oysters was compared to haemolymph from non-exposed controls by 2-dimensional electrophoresis to identify differentially expressed proteins. Differential proteins were subsequently characterised using tandem mass spectrometry (LC-MS/MS) so that their putative biological functions could be assigned.
The data suggest that there are unique protein expression profiles not only for each metal, but at each concentration of metal. Exposure to 100 µg/l of copper, lead and zinc yielded a total of 21 differentially expressed proteins. Only one of these proteins was common to all three metals. Differentially expressed proteins were putatively assigned 11 different biological functions, of which cytoskeletal activity accounted for 25%. Ongoing work includes testing the efficacy of these potential protein biomarkers in the natural environment using oyster samples from field studies conducted in Lake Macquarie, NSW, Australia.

**ET08A-2**

**Searching for stable biomarkers of malachite green exposure in Pangasianodon hypophthalmus by a non invasive approach**

MA Pierrard[1], P Kestemont[2], E Delaive[3], M Dieu[3], P Nguyen Thanh[4], M Raes[3], F Silvestre[2]

[1]FUNDP, NAMUR, Belgium
[2]URBO-FUNDP, NAMUR, Belgium
[3]URBC - FUNDP, NAMUR, Belgium
[4]College of Aquaculture and Fisheries, CANTHO, Vietnam
This study aims at identifying sensitive multibiomarkers of malachite green (MG) exposure in the Asian catfish, Pangasianodon hypophthalmus, one of the most economically important farmed fish worldwide, by a non invasive sampling of peripheral blood mononuclear cells (PBMCs). Despite the fact that MG is banned in fish produced for consumption, this antiseptic is still commonly used in many fish farms. We tried to obtain a signature of protein expression which could work as an early warning signal of MG application even one month after the end of the exposure. The final objective is to apply this biomarker signature to an in situ monitoring. PBMC proteome has the advantage to be subject to rapid changes in response to external signals and enables regular samplings by a non invasive way. A classic (0.1ppm) dose for therapeutic treatment was applied twice, like Vietnamese farmers application. Directly after the second bath (T1) and after 1 month of decontamination (T2), blood was sampled on 3 fish per tank and PBMC were isolated and finally suspended in DLA buffer for proteomic analysis in Belgium. Two-dimensional differential in gel electrophoresis (2D DIGE) were performed on 24cm, gradient acrylamid 8-13.5 %, pH 4-7, IPG strips followed by analysis with DeCyder software. The number of spots matched in the eight gels was 1195 ± 364 in which 116 showed significant differences in intensity between the treated and the controls and which are common for both periods of sampling with no effect of sampling time (Anova 2, n = 4). Considering single identification per spot, we identified by LC-MS/MS 26 different proteins which are mainly involved in energetic metabolism, protein folding, oxidative stress and DNA/RNA binding. To name just a few, Proline 4-hydroxylase and Pre-mRNA-splicing factor are under-expressed 5.84 and 1.34 times respectively at T2 ($p<0.05$). These identified proteins are suggested to be potential candidates for a Biomaker Protein Expression Signature (BPES) since their expression is still modified one month after the exposure, making them quite stable over a decontamination period. In the opposite, assays of MG residues in the muscle and in the blood of fish show that even if leuco-malachite green is more persistent in the muscle, it has almost totally disappeared after one month of decontamination. These promising results open a new way to the application of fish mononuclear cells to find potential biomarkers of exposure in a non invasive way.

**ET08A-3**

**Analysis of effects of herbicide exposure on Chlamydomonas reinhardtii using a multiple endpoint assay and proteomic profiling**

JF Suter, H Nestler, R Schoenenberger
Eawag, DUEBENDORF, Switzerland

Herbicides are a heterogenous group of compounds affecting photosynthetic organisms via a wide range of mode of actions such as the inhibition of photosynthetic electron transport or of carotenoid synthesis. For a comprehensive analysis of the effects of three selected herbicides (diuron, norflurazon, paraquat), each representing one specific mode of toxic action, on the single celled green alga Chlamydomonas reinhardtii we developed a multiple endpoint assay. It comprises measuring a combination of physiological endpoints covering a range of cellular parameters in relatively simple setups. These endpoints are, among others, the application of PAM fluorometry, the assessment of cellular esterase activity using the fluorescent reporter dye CFDA-AM, and determination of ATP levels. The presented approach allows discriminating different herbicide modes of action and studying the endpoints' respective sensitivity towards exposure effects assessment and their correlations among each other.

This assay also revealed suitable exposure conditions for sampling for a proteomic profiling analysis applying 2D-LC-MS/MS in combination with the semiquantitative spectral counting approach. The application of proteomics and other OMICS type analyses in ecotoxicology generally aims at linking the physiological effects and modes of action of toxicants to variations in the target organism's proteome. Of special interest are conditions around the lowest observed effect concentration. Exposure of C. reinhardtii to the above-mentioned model herbicides caused a variety of significant positive and negative changes on the proteome level leading to identification of candidate protein biomarkers for the applied conditions. These biomarkers include enzymes involved in antioxidant defense such as L-ascorbate peroxidase and thioredoxins, photosystem I and II components, proteins controlling posttranslational modifications, and general metabolic pathways such as amino acid synthesis and degradation. Functional annotation of the proteomics data was achieved using the MapMan software platform. It enabled us to determine functional groups, like Calvin cycle or protein degradation, responding to the herbicide exposures. This study provided new insights into the effects of the investigated herbicides and shows the possibility of linking variations on the proteome level with their physiological effects and modes of actions.

**ET08A-4**

**Nuclear proteome changes on the social amoeba Dictyostelium discoideum during the molecular adaptations to environmental stress conditions**

L Boatti, F Marsano, A Negri, A Viarengo
University of Piemonte Orientale, ALESSANDRIA, Italy

The social amoeba *D. discoideum* is a model organism, with a genome fully sequenced, widely used by the scientific community and it is considered as interface between the unicellular and pluricellular organisms.

In the last years we have applied the proteomics approach with 2DE and MS/MS to study the effects induced on the soluble proteins of *D. discoideum* by the exposure to different doses of mercury ($Hg^{2+}$). Marsano et al. (2010) has demonstrated how 10 µM of $Hg^{2+}$ induces in cells a toxicity response with a generally down regulation of the proteins involved in basic physiological processes.

In the present work, to deepen the mechanisms of stress response induced in *D. discoideum* with $Hg^{2+}$ we have analyzed the nuclear proteins changes.

Nuclear proteins modifications represent a crucial point in the actuation of stress response, as can be seen as a hub between signal transduction events and realization of new gene expression/protein synthesis, phenomena which in turn may lead to the establishment of detoxification and adaptation processes to new environmental conditions or to toxicity.

Histones - between the nuclear proteins - are highly conserved and they do not play simply a structural role, but post-translational modifications at specific aminoacid residues can greatly influence gene expression.

The proteins extracted from nuclei of control's cells and treated with 10 µM $Hg^{2+}$ were labeled using the new technique of Isotope-coded protein/peptide label and then analyzed by LC-ESI MS/MS to highlight the main changes induced by treatment on histones and other nuclear proteins in addition to the main post-translational modifications.

We have identified 170 proteins involved in nuclear processes, such us the DNA and/or RNA processing and we have quantified 150 proteins. Data showed that the exposure of Dictyostelium to 10 µM $Hg^{2+}$ induces a down regulation of the nuclear proteins that are directly involved in major biological events - DNA topoisomerase I & II, ADP-ribosyltransferase, RNA polymerase II and all histones of the nucleosome - and they are indispensable during development and cell division in the organisms.

Also, we have found that the treatment with high dose of $Hg^{2+}$ induces post-translational modifications of histones.

In conclusion, these data represent an important link between genomics and proteomics and provide interesting information on the control of regulation of gene expression in D. discoideum when subjected to environmental stressors.

**ET08A-5**

**Measurement of vitellogenin protein in invertebrates : relevance and usefulness of mass spectrometry (LC-MS/MS) to propose a specific and transferable method across species**

G Jubeaux[1], F Audouard-Combe[1], R Simon[2], R Tutundjian[1], H Quéau[1], A Salvador[1], J Garric[1], O Geffard[1], A Chaumot[1]
[1]Cemagref, LYON, France
[2]Université Lyon1, VILLEURBANNE, France

Reproductive success of organisms is related to the quantity and quality of eggs produced by females. Vitellogenin (Vg), precursor molecule of vitellin that is the energy available for embryonic development in oviparous organisms, is proposed as a relevant exposure and effect bio-chemical marker of endocrine disruptors in aquatic vertebrate species (e.g. fish, amphibian). Numerous strategies, such as enzyme-linked immunosorbent assays have been developed to characterise and quantify this protein in vertebrates. On the contrary, in invertebrates few methods are available. This gap mainly results from the low transferability of available antibodies in relation to phylogenetic distance and molecular divergence accumulated by proteins through animal evolution. Recently, our laboratory developed a quantitative assay of Vg in a widespread amphipod, Gammarus fossarum, using liquid chromatography tandem mass spectrometry (LC-MS/MS). This method offers the possibility to identify and quantify Vg, based only on the quantification of proteotypic peptides containing from 5 to 15 amino-acids. Despite a high molecular divergence observed for this type of protein throughout animal evolution, comparative and evolutive genomics revealed that partial conservation between homologous proteins can persist due to high functional constraints acting on residues clustered in the proteic structure forming conserved peptides within phylogenetical groups. In this context, the aim of this study was to assess the possibility to take advantage of peptidic motifs conservation to propose a transferable method across species. For this, our study focused on three model species for which sequence of egg yolk protein is well known, an amphipod, Gammarus fossarum, a cladocerean Daphnia magna and an insect Drosophila melanogaster. In first step, proteotypic peptides of Vg were identified for each species. In the second step, we tried to find these proteotypic peptides in closely related species, such as G. pulex, G. wautierii, D. pulex. This study showed the high relevance of mass spectrometry to propose a specific methodology for Vg measurement. Moreover, methodology proposed to Vg measurement is transferable from a species to another one from the same genus.

**ET08A-6**

**Molecular responses of lymphocytes in European eel Anguilla anguilla exposed to perfluorooctane sulfonate (PFOS). Biomarker discovery using a sub-proteomic approach**

KR Roland, PK Kestemont, AP Pierrard, MD Dieu, MR Raes
FUNDP, NAMUR, Belgium

Since the 1980s, the stocks of European eel have been declining in most of their geographical distribution area and they are now considered below safe limits for population survival. Many factors can be attributed to this decline such as pollution by xenobiotics like PFOS. The aim of this research project was to develop a multi-biomarker approach to set up an evaluation and monitoring tool for assessing the health state of eels. The strategy consists in assessing protein expression profiles (PEPs) in post-nuclear fraction of lymphocytes exposed in vitro to different pollutants, before in vivo validation of biomarkers. The first step of this approach was to find out PEPs of PFOS exposure. For that, we used lymphocyte culture from eel to test the in vitro toxicity of this compound. Exposure time and two sub-lethal concentrations were chosen to avoid cell mortality (48h exposure at 10 µg/l and 1 mg/l). Lymphocytes were isolated from blood by centrifugation over a Ficoll/Hypaque gradient. After in vitro contaminations, the post-nuclear fraction was isolated. Two-dimensional differential in-gel electrophoresis was performed on 24cm, pH 4-7 IPG strips and the results were analysed with DeCyder software. The number of spots detected in the 6 gels was 1665 ± 350, in which 267 ($p<0.05$) and 175 ($p<0.01$) spots showed significant differences between treatments (Anova 1, n=4). The identified differentially expressed proteins can be categorized into diverse functional classes, related to cell structure (e.g. supervillin), protein folding (e.g. protein disulfide isomerase) and signal transduction (e.g. 14-3-3 protein epsilon) for instance with some proteins never found in proteomic studies. These promising results are expected to point out potential biomarkers of exposure to PFOS on fish lymphocytes as well as to highlight unknown mechanisms of action of this pollutant. The second step will be in vivo contaminations of eels in order to validate the PEPs previously defined.

**ET08B-1**

**The Estuarine Sediment Ecology Array (ESEA): a rapid and comprehensive molecular based approach for environmental monitoring and assessment**

AA Chariton[1], L Court[2], M Colloff[2], M Morgan[2], C Hardy[2]
[1]CSIRO, KIRRAWEE, Australia
[2]CSIRO Environmental Services, CANBERRA, Australia

Ecological assessments of estuarine environments are restricted to the examination of a small number of macrobenthic taxa, providing a narrow view of a system's true diversity. This is despite strong evidence that many other biotic groups, e.g. meiofauna, may be better indicators of environmental change and condition. However, their inclusion is generally considered too difficult to be routinely practical. The fundamental approaches for assessing and monitoring sedimentary environments has changed little for many decades. Recent advancements in the molecular sciences provide a unique opportunity to measure and understand biological complexity at a previously unattainable level. We have developed a novel approach for sediment ecological assessment, the Estuarine Sediment Ecology Array (ESEA). ESEA is a custom-designed microarray which contains phylogenetically diagnostic gene probes which can be used to identify the presence of an extensive range of organisms ranging from microorganisms to macrobenthic fauna. The underlying approach behind the ESEA is that DNA is extracted from sediments, targeted genes are amplified and hybridized against the array. When the sample's sequences match those on the array, fluorescence signals are produced and the intensities measured. Each probe set is annotated with taxonomic information, enabling rapid identification of a sample's biota. Genes used to create the array were derived from a pyrosequencing study of Sydney Harbour and from

GenBank, an online gene repository. Cross-reaction probe sets were also created for the detection of taxa not specifically represented on the array. The ESEA contains >250,000 probes designed to encapsulate over 53,000 gene sequences. Laboratory trials clearly demonstrated the array's viability. Field trials were performed on eukaryotic meiobiota assemblages sampled from reference and contaminated locations. The results revealed marked differences in the biota between the two treatments, with comparisons involving several thousand taxa. The ESEA has been calibrated and cross checked using pyrosequenced data derived from the same DNA extracts, with extensive field trials currently being performed. The application of ESEA and other genomic technologies now makes it possible to rapidly and comprehensively examine the biological constituents of an environment at a cost similar to that of traditional taxa focussed optical based techniques.

**ET08B-2**

**The DanTox-Project - identification of specific toxicity and molecular modes of action of sediment-bound pollutants in zebrafish**

H Keiter[1], S Peddinghaus[1], J Bräunig[1], U Feiler[2], C Hafner[3], M Hammers-Wirtz[4], NY Ho[5], B Kais[6], JC Otte[5], R Ottermanns[4], S Rastegar[5], G Reifferscheid[2], T Braunbeck[6], U Strähle[5], H Hollert[7]
[1]Institute for environmental research, AACHEN, Germany
[2]German Federal Institute for Hydrology, KOBLENZ, Germany
[3]Hydrotox GmbH, FREIBURG, Germany
[4]Research Institute GAIAC, AACHEN, Germany
[5]Karlsruhe Institute of Technology, Institute of Toxicology and Genetics, KARLSRUHE, Germany
[6]Aquatic Ecology and Toxicology Group, University of Heidelberg, HEIDELBERG, Germany
[7]Institute for Environmental Research, RWTH Aachen University, AACHEN, Germany

The aims of the DanTox project are a) to develop a suitable testing strategy for the assessment of bioavailable toxicants in sediments, b) to investigate the molecular and cellular mechanisms of sediment toxicity, and c) to elucidate the causality of biological effects. The long-term objective will be the development of a targeted cDNA-microarray which will be a useful tool for environmental screening.

Sediment samples were collected from the Rhine River (Altrip and Ehrenbreitstein) and from the Vering Canal in Hamburg. For the testing of model chemicals methylmercury(II)-chloride, chlorpyrifos, Aroclor 1254 and bisphenol A were selected. The different methods of the project are categorized into four modules: a) bioassays - selected biomarkers and endpoints; b) gene expression - microarrays and qRT-PCR; c) data assessment - statistical evaluation of the data; d) practical transfer - comparison of the results from sediment contact tests and guideline tests.

At the present stage of the project, results from the fish embryo test, EROD assay, live-imaging of EROD induction and qRT-PCR analysis are available. The highest embryotoxic potential was measured for the sample from Vering Canal after 48 h of exposure (EC50 = 2.6 and 3.6 mg/ml for extract and native sediments, respectively). EC50s for the extracts from Ehrenbreitstein (EC50 = 21.7 mg/ml) and Altrip (EC50 = 18.1 mg/ml) suggest that there is a comparable embryotoxic hazard potential. Only minor EROD induction was measured for TCDD suggesting that the barrier function of the chorion prevents TCDD from harming the embryo. In contrast, sediment extracts showed a clear dose-response-depending EROD induction. Live-imaging of EROD induction with β-naphtoflavone as a positive control documented CYP1 induction at any time of inspection. Due to their molecular structure, methylmercury(II)chloride and chlorpyrifos showed no EROD induction. qRT-PCR revealed clear changes in the transcript abundance of CYP1A1, GST and UGT1A1 genes for the sediment extracts. Up to 600-fold changes in CYP1A1 could be seen for the extract from Vering Canal.

First results from the biotest systems indicate that measurement of specific endpoints is a suitable strategy to identify and detect the bioavailable hazard potential of sediments. In addition, a comparison of the results from the EROD assay and qRT-PCR showed similar tendencies for the sediments indicating that the EROD assay with zebrafish could be a useful tool for routine testing.

**ET08B-3**

**The future role of next-generation DNA sequencing and metagenetics in aquatic biological monitoring programs**

EM Pilgrim, S Jackson, J Martinson, J Darling
United States Environmental Protection Agency, CINCINNATI, United States of America

The development of current biological monitoring and bioassessment programs was a drastic improvement over previous programs created for monitoring a limited number of specific chemical pollutants. Although these assessment programs are better designed to address the transient and potentially syngeristic nature of environmental stressors, the reliance on morphological taxonomic identification of samples has several inherent issues limiting the scope of these programs. Biological monitoring programs suffer from high costs, long completion times, quality assurance issues from taxonomic disagreements, and reliance on 'large' animal groups, such as fish and macroinvertebrates, that can be identified by experts. Neglected communities such as microbiota and meiofauna represent a wealth of information that could be applied to assessing ecological condition. Even for those fauna used in bioassessment, many taxa are not readily identified to species, leading to taxonomic impresicion and a potential loss of information. Next generation DNA sequencing (NGS) is a revolutionary technology when considered in the context of biological monitoring programs. This technology allows for bulk DNA extraction of virtually all the specimens in a sample, followed by DNA sequencing of genetic loci used for taxonomic identification. NGS generates large amounts of sequence data that can be applied not only to the identification, with finer taxonomic resolution, of those groups currently used in assessment, but to previously intractable groups such as nematodes, diatoms and other algae, protozoans, and other meiofaunal invertebrate phyla. This presentation will outline the future role that metagenetic data generated by NGS could have in new biological monitoring and assessment programs. The future uses of this metagenetic data would be not only to improve the speed and precision of biological monitoring, but to move programs beyond relatively simple conditions assessments (often 'good,' 'fair,' or 'poor') to the ultimate goal of bioassessment: environmental stressor identification. We will duiscuss the current state of technology, planned research, and future hurdles for the use of metagenetic data in freshwater and marine biological monitoring programs.

**ET08B-4**

**Enchytraeid transcriptome sequencing towards the establishment of a soil ecotoxicogenomics model**

MP Castro-Ferreira[1], CAM van Gestel[2], J Colbourne[3], AMVM Soares[4], MJB Amorim[4], D Roelofs[5]
[1]Vrije Universiteit Amsterdam, AMSTERDAM, The Netherlands
[2]Vrije Univ Amsterdam, Dpt Anim Ecology, AMSTERDAM, The Netherlands
[3]Center for Genomics and Bioinformatics, Indiana University, BLOOMINGTON, United States of America
[4]Biology department, University of Aveiro, AVEIRO, Portugal
[5]Animal Ecology department, Vrije Universiteit Amsterdam, AMSTERDAM, The Netherlands

Enchytraeids are an ecologically relevant functional group of the soil mesofauna, distributed globally and present in most soil types. *Enchytraeus crypticus* is a bio-indicator potworm frequently used in soil ecotoxicological tests. The importance of this soil ecotoxicological model is reflected in the establishment of an ISO guideline (ISO16387, 2010) and an OECD guideline (OECD 220, 2004). The drawback is that ecotoxicological testing is time-consuming, labour-intensive and considers endpoints as survival and reproduction thus not informing on the mechanism of toxicity. Alternatively, transcriptional responses are usually fast and provide mechanistic information on the toxic compound. Transcriptomic analyses require sequence information, but this is absolutely lacking for *E. crypticus*. Therefore we present data on transcriptome sequencing of *E. crypticus* using next-generation sequencing technology. The effect concentrations affecting *E. crypticus* survival and reproduction endpoints for five key chemicals were empirically assessed via standard ecotoxicological testing (ISO 16387, 2010; OECD 220, 2004). The EC50 for *E. crypticus* reproduction after 21 days of exposure in LUFA 2.2 soil spiked with carbendazim, cadmium, phenanthrene, 3,5-dichloroaniline and pentachloroaniline were, respectively, <1.0, 35.0, 144, 101 and 278 mg a.i/kg d.w. LUFA soil. Comparing to *F. candida*, the enchytraeid was more sensitive to metals but less susceptible to organic compounds. The different sensitivity of *E. crypticus* emphasizes its relevance as soil ecotoxicological model. In order to obtain most enchytraeid transcriptome information, *E. crypticus* was short-term exposed to the five chemicals at distinct effect concentrations, as well as distinct soil moisture, temperature and pH values. Also, samples from distinct developmental stages and starved animals were taken. The RNA pool, composed of transcripts from above mentioned treatments, was normalized prior to ultra-high throughput 454 Roche GS FLX Titanium pyrosequencing. Approximately 1 million output reads were assembled using distinct programs and the assemblies were combined in order to reach more consistent contigs representing putative transcripts. We performed functional annotation of identified transcripts and linked the obtained biological processes to the applied treatments. This is a crucial first step towards understanding and modelling the mechanistic basis of toxic effects occurring in the enchytraeid.

[4]McMaster University, HAMILTON, Canada
[5]Parks Canada, FORT SMITH, Canada
[6]Environment Canada, FREDERICTON, Canada

Biomonitoring seeks to describe and understand biological diversity at different locations, both as a means to learn the typical mix of species that can be found in different habitats, and to establish biological early-warning systems that can indicate when environmental stresses are reaching a critical point. Canada is recognised as a world leader in biomonitoring, but current practices are personnel-intensive, limiting the frequency and intensity of sampling, particularly in remote areas, and focus on a very limited subset of all species that can be found at a given location. Our project introduces 'Biomonitoring 2.0', a DNA-based system utilizing new next-generation sequencing (NGS) technologies and advanced computational analysis, that will simultaneously reduce sample costs while dramatically increasing the knowledge gained from biological samples. Ecosystems are sampled using a multi-habitat approach, and the resulting bulk samples presented for rapid NGS analysis. Using a multi-gene approach, linked to an advanced bioinformatics platform and associated cyberinfrastructure, we can rapidly sort and identify organisms, providing a rich information source for environmental assessment. We are applying this new system in Canada's Wood Buffalo National Park, a World heritage area, containing two internationally-important Ramsar wetlands that are currently threatened by climate change, oil sands extraction, hydro-electric schemes, mining and other human impacts. The project will produce an information source which can be used to develop advanced environmental diagnostics system, to assess the relative contribution of multiple stressors operating on the landscape at different temporal and spatial scales. These stressors include climate-related variables relating to drought (temperature, oxygen, hydroperiod) and contaminants from upstream oil sands activities (including metals and PAHs).

**ET08B-6**

**Relationship between metal bioaccumulation, gene expression and toxic responses in early life stages of Japanese medaka exposed to cadmium-spiked sediments**

IS Barjhoux[1], M Baudrimont[1], B Morin[1], P Gonzalez[1], J Cachot[1], A Pichon[2]
[1]University Bordeaux 1, TALENCE, France
[2]University bordeaux1, TALENCE, France

Aquatic sediments are well known sinks for numerous persitent pollutants such as POPs and heavy metals. Sediment-accumulated pollutants can be partially bioavailable and may represent a threat for benthic organisms in particular at pollutant-sensitive early life stage. In order to evaluate impact of contaminated sediments on early developmental stage of fish, Japanese medaka embryos were exposed during their whole embryonic development to cadmium-spiked sediments at two environmental concentrations (2 and 20µg/g d.w.). Bioaccumulation, metallothioneins (MTs) content and gene expression levels (rRT-PCR) were assessed at the end of organogenesis (7days post-fertilization) and at hatching. In addition, non invasive endpoints including cardiac activity, developmental abnormalities, body size and survival were examinated during experiment. Results showed significant differences in Cd bioaccumulation levels according to developmental stages and exposure concentrations. Although a dose-dependent accumulation of Cd was reported, no effect on either MTs proteins or mt gene expression was observed. In contrast, morphological deformities mainly on spine column and cardio-vascular system were increased following Cd contamination. Genotoxic potency of tested heavy metal was confirmed by DNA repair, oxydative stress defense system and apoptosis related genes overexpression. Moreover and for the first time, a parallel increase of wnt1 expression was highlighted in Cd-exposed prolarvae.

This study evidenced significant bioaccumulation and effects of cadmium in early developmental stage of medaka following realistic exposure to environmental concentrations of Cd. The same experimental protocol can be used to monitor effect of various sediment-associated pollutants including heavy metals and POPs. Associating early response markers and phentotypical effects observation may improve risk assessment of environmentally persistent chemicals.

## ET09 - Laboratory and field measurements and alternative approaches in bioaccumulation

**ET09-1**

**Relating field bioaccumulation metrics for chemicals in a benthic and pelagic food web with existing bioconcentration data**

P Leonards[1], S van Leeuwen[1], B van Hattum[1], F Gobas[2], H Leslie[1]
[1]VU University, Institute for Environmental Studies, AMSTERDAM, The Netherlands
[2]Simon Fraser University, BURNABY BC, Canada

The current state of bioaccumulation science relies heavily on fish bioconcentration (BCF) testing according to international protocols in order to predict the level of bioaccumulation of chemicals in real organisms in food webs in the field. How similar are BCFs measured in the laboratory to BAF measured in the field? Predictions of bioaccumulation in the field of xenobiotic chemical substances are based on standard bioconcentration (BCF) tests or estimated using regression equations. How easily can we use BCF to predict the behaviour in the field of new chemicals which lack field data so far? How chemicals partition between water and biota, between biota and air are important processes in the understanding of bioaccumulation in food chains and are key to the translation of BCF tests to bioaccumulation in the field. To study bioaccumulation in the field, the Western Scheldt estuary in The Netherlands was selected, as this estuary is characterized by a large land-based pollutant input. We present here examples of how different chemicals, with a wide range of Koa, Kow, and biotransformation rates, bioaccumulate and biomagnify in the pelagic and benthic food chains within this food web, including an air-breathing top predator species (tern). The data illustrates the impact of including bioavailability in the water phase on the calculations of bioaccumulation metrics such as BAF as well as the impact of biotransformation on the biomagnifications (BMF) and trophic magnification factors (TMF). First of all, BCF values are subject to variability (due to protocols followed, but also species-specific differences). When the BAF is examined, we can see that for some compounds, such as PFOA, that the median BAF value is very low (79), however the TMF is >1 in the benthic food web, suggesting biomagnification. The importance of biotransformation as important factor impacting the bioaccumulation of chemicals in a food chain was examined in relation to the BCF, BAF, BMF and TMFs. Biotransformation can have a major impact on bioconcentration and field bioaccumulation as we have seen in the examples of pyrene and BDE209. This also contributes to a low TMF: trophic dilution. Also, the use of dissolved concentrations for these chemicals was demonstrated to have an impact on the BAF calculated in the field. The food web studies demonstrate several key factors for the interpretation of laboratory and field bioaccumulation metrics.

**ET09-2**

**Reducing uncertainty in risk assessment: lessons learned from studying sediment-associated fragrance materials**

H Selck[1], D Salvito[2], VE Forbes[1]
[1]Roskilde University, ROSKILDE, Denmark
[2]Research Inst for Fragrance Materials, WOODCLIFF LAKE, NJ, United States of America

Being able to accurately identify PBT substances is key to protecting human health and the environment. Potential hazards and risks of new and existing chemicals are assessed by regulatory agencies based on their P (persistance), B (bioaccumulation) and T (toxicity) potential, and if a compound is characterized as PBT it may be subjected to regulatory control or further characterization to determine its harmfulness. The focus of this presentation will be on the importance of environmental and physiological factors for affecting bioaccumulation, including biotransformation, of organic contaminants in the aquatic environment and thus the importance of these factors for contaminant persistence. Examples will include results from a range of experiments performed in collaboration with the Research Inst. for Fragrance Materials (RIFM) using different sediment-associated fragrance materials (FMs), sediment-dwelling deposit-feeders and different sediment organic contents. Here we focus on: 1. effects of varying organic matter content in the sediment; and 2. impact of species dependent biotransformation differences for the fate (accumulation, biotransformation) of sediment-associated FMs. These studies support the conclusion that the materials presented int he examples are not PBTs.

Due to their feeding strategy, that involves ingesting massive volumes of sediment, and a digestive system optimized to extract organic material from sediment, deposit-feeders may take up large amounts of contaminants from the gut during feeding. However, since at least some deposit feeders also show high biotransformation capacities, which evidently will reduce the body-burden (BB) of organic contaminants, focusing solely on BB will significantly underestimate accumulation and thus increase the uncertainty of e.g., BAF. Since benthic communities play an important role both in the remobilization of sediment-associated organic compounds and in other fate processes (biotransformation) there are implications for the way we evaluate the persistence of organic contaminants in risk assessment. Based on the lessons learned, uncertainty in risk assessment can be reduced by focusing future research on physiological properties that impact accumulation and biotransformation of B and P substances.

**ET09-3**

**Effects of habitat and season on food web accumulation of cadmium to the little owl: a modelling study based on field data**

W van den Brink[1], AM Schipper[2], S Wijnhoven[3], JM Baveco[1]
[1]Alterra, Wageningen UR, WAGENINGEN, The Netherlands
[2]Radboud University, NIJMEGEN, The Netherlands
[3]Netherlands Institute of Ecology, YERSEKE, The Netherlands

Little owls (Athene noctua) inhabit different habitats, including floodplains, and have a wide range of potential diet items. However, floodplains are contaminated by legacy contaminants, which may pose a toxicological risk to the little owl. It has been shown that accumulation patterns may differ within floodplains, due to spatial variation in habitat characteristics, soil concentrations and the occurrence of prey items. Field observations showed high seasonality in the occurrence of prey items, so in addition to spatial variation, contaminant accumulation to the little owl is expected to vary temporally, related to this seasonality in diet composition. Modelled exposure of little owls to cadmium indeed showed considerable seasonal and spatial variation. Calculated geometric mean exposure levels were well below threshold levels. However, due to the seasonal variation in diet composition, exposure levels exceeded the threshold values in both spring and fall for a prolonged period of time. This would indicate risks at those moments, which is in contrast with the conclusion based on the geometric mean value. Especially the fact that the threshold is exceeded during the spring period may be of importance, since that is the period of chick rearing. This would have been missed assuming fixed dietary fractions throughout the year, which may underestimate seasonally occurring risks. This presentation illustrates the potential of habitat and season specific food web modelling for more adequate assessments of risks of environmental contaminants to wildlife.

**ET09-4**

**Capacities of phospholipid membrane to accumulate neutral organic chemicals**

S Endo[1], B Escher[2], KU Goss[1]
[1]Helmholtz Centre for Environmental Research - UFZ, LEIPZIG, Germany
[2]University of Queensland, National Research Centre for Environmental Toxicology, BRISBANE, Australia

Lipids have been considered as the predominant components for accumulation of organic chemicals in biota. It is a common practice to normalize chemical concentrations in the organism to the total lipid content regardless of the classes of chemicals. However, there are at least two types of lipids that are present amply in organisms, storage and membrane lipids. Despite the obvious structural differences between the two types of lipid, their differences in accumulation properties have not systematically been addressed. This study focuses on the equilibrium partition coefficients ($K$) of neutral organic compounds into phospholipid membrane. We critically evaluated literature liposome-water partition coefficients ($K_{lipw}$) for neutral compounds and evaluated methods to estimate $K_{lipw}$.

There was a fairly good correlation between log $K_{lipw}$ and log $K_{ow}$. Errors were typically up to ± 1 log untis, although there was considerably larger scattering in the region of log $K_{ow}$ > 6, due primarily to the too small $K_{lipw}$ values for PCBs from early studies. However, even recent $K_{lipw}$ values measured by polymer-mediated sampling methods exhibited 1-2 log unit differences between PAHs and PCBs of comparable Kow. Alternatively, polyparameter linear free energy relationships (PP-LFERs) were used for both consistency test and $K_{lipw}$ estimation. The PP-LFERs fit well to the collected $K_{lipw}$ data ($R^2 = 0.97$; standard devation, 0.3 log units). In contrast to the $K_{ow}$ model, the recent values for both PAHs and PCBs fit well to the regression equation without any indication of the 'hydrophobicity cut-off' proposed previously by others. These results suggest that PP-LFERs can be highly useful for Klipw estimation.

Using the PP-LFER for $K_{lipw}$ obtained, $K$ values representative for membrane lipid-water partitioning were calculated for a number of compounds. Similarly, $K$ values from water to storage lipid were estimated using the PP-LFER for olive oil-water partition coefficients. The comparison suggests that $K$ between both lipids differ by only < 1 log unit for low-polarity compounds (e.g., PAHs) and H-bond-acceptor monopolar compounds (e.g., nitrobenzenes). In contrast, bipolar compounds (e.g., phenols) generally favor membrane lipid over storage lipid and the resulting $K$ values can be > 1 log unit different. Thus, the "total lipid"may not be a suitable normalizer for bipolar compounds, which include a number of compounds such as those with -OH.

The efficient assessment of the bioaccumulation potential of chemicals under REACH with integrated test strategies (ITS) requires multiple tools. Existing data have to be searched and information from chemical structures and physico-chemical properties need to be evaluated prior to considering to conduct in-vivo experiments with vertebrates. The OSIRIS inventory of chemistry-driven and in-silico BCF modules for ITS compiles:

· Sources of existing data
· Computational methods
- B/nonB classification models
- QSARs
- Physiological models
- Exposure models
- Read across
· in-vitro tools
· 3R (Refine, Reduce, Replace) modules

The ITS components for bioaccumulation listed in the ECHA Guidance on information requirements and chemical safety assessment [1,2] have been extended with new knowledge generated in OSIRIS and complemented with feedback from stakeholders on the actual problems in using ITS for chemical registration. The alternative ITS modules share three major objectives to save time and money by reducing the number of experimental animals required to come to a conclusion about the bioaccumulation potential of chemicals under REACH:

· Classification of non-B/B/vB-compounds
· Omission of BCF studies, that are scientifically unnecessary or technically not feasible
· Waiving of BCF studies, that provide no risk-relevant information

The OSIRIS ITS for bioaccumulation will be publicly available (webtool) after further refinement based on stakeholder feedback. Its concepts and modules, as well as validation results, are presented in detail in a dedicated poster corner.

**Fishing for contaminants in McMurdo Sound, Antarctica: measuring physiological responses of PBDE exposure in Trematomus bernacchii**

RG Ghosh[1], KJH Hageman[1], ML Lokman[1], ML Lamare[1], VM Metcalf[2], WD Davison[3]
[1]University of Otago, DUNEDIN, New Zealand
[2]Lincoln University, CANTERBURY, New Zealand
[3]University of Canterbury, CANTERBURY, New Zealand

Polybrominated diphenyl ethers (PBDEs), which are flame retardants, have been detected at the Antarctic research bases, McMurdo Station and Scott Base. They have also been detected in marine organisms nearby and their presence has been attributed to the sewage sludge released from the research bases. Although there are several published studies showing the toxic effects of both PCBs and PBDEs on temperate fish, nothing is known about the effects of PBDEs on polar fish. Our *main objective* was to determine physiological responses of Antarctic fish, *Trematomus bernacchii*, exposed to two different sub-chronic doses of a PBDE congener mix. Physiological responses were assessed by (a) analysing morphometric data and liver histology and (b) measuring the relative expression of mRNA of cytochrome P450 1A-1 (CYP1A-1) and Cu,Zn superoxide dismutase (Cu,Zn SOD) using quantitative polymerase chain reaction (qPCR).
Live fish were captured at Cape Evans, Antarctica and transported to New Zealand for a ten-week dose-response study. Baseline samples consisted of fish euthanized in Antarctica and fish transported to New Zealand and then euthanized; these fish were not subjected to dose regimes. All remaining fish were divided into three groups and fed gelatine capsules containing either 0-ng (control), 32-ng (low-dose) or 320-ng (high-dose) of a PBDE mix (congeners 28, 47, 99, 100, 153, 154, 183 and 209). Fish were subjected to fortnightly treatments resulting in each group receiving a total of four treatments. Five fish from each group were euthanized at 14-day intervals, biometric data were collected for morphometric analysis (Fulton condition index), fragments of livers were preserved for histology analysis and 60-mg of liver tissue was snap frozen for molecular analysis.
Fulton condition index showed a significant decrease in fish from low- and high- dose groups in comparison to the control group, $F_{2,\,42}=3.826$, $p<0.05$. Liver histology indicated a decrease in lipid abundance in the high-dose animals with increasing number of treatments. Furthermore, two-way ANOVA found a significant increase of the normalized mRNA levels of CYP1A-1 in the high-dose group with time ($F_{2,\,42}=6.128$, $p<0.05$) but not for Cu,Zn SOD. Future research includes measuring (a) lipid amounts in liver to determine variation in lipid content in different treatment groups and (b) enzymes involved in the defence against oxidative stress such as catalase and glutathione peroxidise using protein assays.

### ET10A-2

**Exposure to EDCs Disrupts the Expression of cyp19a Isoforms of the Murray River rainbowfish, Melanotaenia fluviatilis**

AH Shanthanagouda[1], G Patil[2], D Nugegoda[1]
[1]RMIT University, BUNDOORA, Australia
[2]Inland Fisheries Service, NEW NORFOLK, TASMANIA, Australia

Cytochrome P450 aromatase is the only steroidogenic enzyme activating the synthesis of estrogens from aromatisable androgens and plays a key role in neural development, sex differentiation, sexual/mating behaviours, reproductive cycles and also in other physiological functions. This study investigated the influence of two endocrine disrupting chemicals (EDCs) exogenous oestrogen 17beta-oestradiol (E2) and the estrogen mimic Bisphenol A (BPA) on the expression of cyp19a isoforms in both sexes of adult Murray River rainbowfish. Reproductively active male and female fish were exposed to either 1, 3, 5 μg/L of E2 or 100, 500 μg/L of BPA for 96 h. The expression analyses of cyp19a isoforms in the brain and gonads were studied using quantitative Real-Time PCR (qPCR). cyp19a1a expression in the ovarian tissues was downregulated and inhibited with E2 exposures. Whereas, it was upregulated until 48 h and reduced at 72 and 96 h with BPA exposure. However, its expression was not detected in the tissues including testes and the brain of both sexes. The expression of cyp19a1b in the female fish brain was upregulated until 48 h and reduced at 72 and 96 h with both EDCs. However, its (cyp19a1b) expression was suppressed with E2 and elevated with BPA exposures in brain of male fish. We also studied the expression of cyp19a1b in the gonads of both sexes where cyp19a1b in the ovarian tissue was downregulated with both EDCs exposure. Meanwhile, its expression in the testes was upregulated with E2 and suppressed with BPA exposure throughout the exposure period. The results showed that E2 and BPA regulate expression of cyp19a isoforms via both positive and negative feedback mechanisms. The results support the hypothesis that the expression of cyp19a isoforms depend on the duration of exposures, tissue and sex of the fish. Collectively the results suggest that, E2 and BPA can have a disruptive effect on the steroidogenic pathways and hence sexual/mating behaviours, sex differentiation and reproductive cycles in this fish.

### ET10A-3

**A link between environmental contaminants in Southern Alberta Rivers and physiological consequences disrupting reproduction and metabolism in fish**

R Habibi, A Zare, J Jordan, A Weljie, LJ Jackson
University of Calgary, CALGARY, Canada

The objective of the present study was to investigate the presence and adverse developmental effects of environmental contaminants in Southern Alberta rivers by means of chemical analysis, field studies and controlled laboratory experiments. Organic contaminants (natural and synthetic steroids, organic compounds and pharmaceuticals) were detected at all sites sampled along the Oldman river, Bow river and Red Deer river. We used longnose dace to investigate a link between exposures to environmental contaminants with biological response. A significant increase in female to male adult ratio was observed in longnose dace caught down stream of certain municipalities. Significant increases in vitellogenin (VTG) expression were observed in male longnose dace in correlation with female-biased sex ratios, suggesting severe endocrine disruption of gonadal development likely due to presence of compounds with estrogen-like activities. The results are consistent with the hypothesis that exogenous factors resulted in sex changes in longnose dace and caused genotypic males to develop as phenotpypic females. To test this hypothesis, we performed controlled laboratory experiments in which fish in aquaria were exposed to the same concentrations of a selected number of chemicals detected in the river system, individually and as mixtures. The results demonstrate that different chemicals present in the Oldman River disrupt the gene expression profile of the liver, ovary and testis, and the action of these contaminants becomes significantly larger when present in mixtures, compared to the effect of compounds individually. To further investigate the mechanisms of endocrine disruption, we have applied 1H-NMR metabolomics as a tool to measure the concentrations of metabolites in the liver and gonad tissue extracts, and evaluated net metabolic dysregulation due to exposure. The results suggest significant dysregulation of amino acid, lipid, energy, carbohydrate, nucleotide and cofactor/vitamin metabolism. The effect of mixture of contaminants on liver was significantly different from all the individual treatments. The results provide novel information on the effect of contaminants individually and in mixture on global metabolism dysregulation in male goldfish and a framework for better understanding of the metabolic pathways affected by environmental contaminants in fish.

### ET10A-4

**Oxidative stress and growth in Alligator Gar exposed to environmentally relevant concentrations of the aquatic herbicide, Diquat.**

V Palace[1], M Beaudry[2], R Campbell[3], B Brian[1], N Nick[1]
[1]Fisheries and Oceans Canada, WINNIPEG, Canada
[2]University of Manitoba, WINNIPEG, Canada
[3]Tupelo Fish Hatchery, TUPELO, United States of America

In Canada Spotted Gar, Lepisosteus oculatus, a species of freshwater fish is known only to three bays of Lake Erie (Long Point, Point Pelee and Rondeau Bay) and is considered a threatened species. The remaining populations are subject to numerous anthropogenic stressors including contaminants, siltation, dredging, and removal of aquatic vegetation through applications of the bipyridal contact aquatic herbicide Diquat (1,1'-ethylene-2,2'-dipyridylium). A potent redox cycler, diquat can increase proliferation of reactive oxygen species leading to cell membrane damage and also potentially impairing growth. During the summer of 2010, water samples collected from a treated area of Rondeau Bay contained 40 _g L-1, 3 hours after treatment, declining to 4 _g L-1 after 24 hours. Diquat was not detected in reference areas. Because experimentation on threatened species is not possible, cultured alligator gar (Atractosteus spatula) were used as a surrogate Lepisosteidian species to examine potential effects of similar diquat concentrations on growth and oxidative stress parameters. Juvenile alligator gar (Xg, n=50/group) were exposed to 0 (reference), 50, 100 or 400 _g L-1 in a static renewal system for a period of 21 days followed by depuration in untreated water. Concentrations of diquat, as well as the metabolites diquat monpyridal and diqaut bipyridal, were quantified (UV/Fluorescence HPLC) in liver immediately after exposure and at 6 weeks post-exposure (n=8/treatment and time). Concentrations of the antioxidant vitamins E (tocopherol) and A (retinoids), as well as peroxidized lipids, were determined in liver as indicators of oxidant damage.

### ET10A-5

**Reduced host resistance against tuberculosis in fish exposed to elevated levels of POPs**

V Berg[1], A Zerihun[2], J Colquhoun[2], T Poppe[2], L Lyche[3]
[1]Norwegian School of Veterinary Science, OSLO, Norway
[2]National Veterinary Institute, POB 8156 Dep., N-0033 Oslo, Norway, OSLO, Norway
[3]The Norwegian School of Veterinary Science, OSLO, Norway

Extremely high levels of polybrominated diphenyl ethers (PBDEs) have been reported in fish from Lake Mjøsa, and also, high concentrations of PBDEs have been detected in humans that consumed fish from the lake. In addition polychlorinated biphenyls (PCBs) and dichlorodiphenyltrichloroethanes (DDTs) are high in fish from Lake Mjøsa while fish from Lake Losna appear to contain background levels of these contaminants in Norway. The high levels of POPs detected in fish in Lake Mjøsa have led to advices from the Norwegian Food Safety Authority, warning children and women in fertile age against eating large trout regularly.
In the present project burbot (*Lota lota*) were sampled from the two lakes. Hepatic levels of POPs and OH metabolites were analysed and the fish were examined for bacterial- and parasite infections and histopathological changes. In accordance with previous studies the levels of PCBs (5310 ng/g lipid weight) and DDTs (3280 ng/g) were 10 times higher, and PBDEs (32900) was 200 times higher, than the corresponding levels in fish from Lake Losna (PCBs 576 ng/g, DDTs 232 ng/g, PBDEs 116 ng/g). To study potential metabolic pathways, OH-metabolites of PCB and PBDEs in blood and bile were analysed. Only 4-OH-CB 146 was found in bile and in blood, and in levels below 2 % of the parent PCB congeners suggesting that the metabolism of PCBs is low in burbot. The level of OH-BDE 49 in blood was approximately 2 % of the corresponding to the level in bile suggesting that bile excretion is the major route of elimination for PBDEs in burbot. The prevalence of pathological lesions (62%) and parasite and *Mycobacterium salmoniphilum* infections (18%) was significant higher in fish from Lake Mjøsa compared to Lake Losna (<1%) suggesting that the high level of contamination in Lake Mjøsa may adversely affect host resistance against opportunistic pathogens.

### ET10A-6

**EROD activity in peripheral blood lymphocytes: a non-invasive and relevant biomarker of exposure of dairy ruminant to PAHs and other POPs**

P Guiavarc'H[1], C Feidt[2], G Rychen[2]
[1]University of Nancy, VANDOEUVRE-LÈS-NANCY, France
[2]ENSAIA, NANCY, France

The use of biomarkers for evaluating the level of exposure of animals to environmental pollutants should be the first step prior to any exhaustive but often time-consuming and expensive analytical investigations (extractions in complex biological matrices followed by LC or GC-MS analysis). In this respect, EROD activity has been extensively used over the past decades as a non specific biomarker of exposure of wild fauna to CYP450 1A1/1B1 inducing persistent organic pollutants (POPs) such as PAHs, PCBs, Dioxins and many over pollutants. In fish, EROD activity is measured in the liver or in the gill tissue. In birds and marine mammals, such as seals or penguins, it is often measured in liver. But EROD activity was also measured in duodenum and kidney of laboratory animals such as minipigs or rodents. To date, there is a total lack of information on the possibility to use this activity as a biomarker to evaluate the level of exposure of dairy ruminants to POPs such as PAHs. This could however be useful since POPs are often lipophilic molecules, which can therefore be transferred toward milk in a metabolized or native form with possible issues in terms of food chain. With such big farm animals (cows, goats or sheeps), EROD activity measurements should of course be performed without slaughter. Since it was shown that EROD activity could also be detected in peripheral blood lymphocytes (PBL) of rodent and humans, we decided to check the possibility to use simple blood samplings.
The first objective of this brief presentation is to introduce kinetic and dose/responses results showing that EROD activity in peripheral blood lymphocytes can be used as a relevant and

non-invasive biomarker of chronic (40-day) dairy ruminant oral exposure to PAHs, using goats as a model species. The second objective of this presentation will be to introduce recent results achieved on PBL of rats orally exposed to PAHs over a 28-days period, with simultaneous comparison of the EROD activity in the liver and brain. These results clearly demonstrate that EROD activity in PBL can be linearly correlated to EROD activity in the liver and in brain, thus strengthening the hypothesis according to which EROD activity in PBL could be used to properly evaluate EROD activity in the liver. This last point is interesting since the liver is the main detoxifying organs.

**ET10B-1**

**Predictors of disease susceptibility in quail (Corturnix sp) exposed to immunotoxic environmental contaminants**

JEG Smits, S Nain
University of Calgary Veterinary Medicine, CALGARY, Canada

We investigated the immune response, physiological markers, plus disease resistance to an infectious agent (E. coli), to characterize the biological costs of exposure to environmental contaminants. Experimental birds (Coturnix c. japonica) were orally exposed to three contaminants of global concern; lead (Pb), malathion (the most widely used organophosphate insecticide in North America), and perfluoroctanoic acid (PFOA). Exposures were environmentally realistic; lead acetate (0, 5, 50ppm), malathion (0, 1, 10ppm) and PFOA (0, 1, 10ppm). Immunity was tested through i) the PHA skin test of T cell response, ii) the antibody mediated B cell response to vaccination with Newcastle Disease Virus, and iii) the innate immune response measured through; iiia)the chemiluminescence assay and iiib) the expression of TLR"ð3 in the bursa of Fabricius. In the PFOA study only, thyroid hormones (T4, T3) were measured in plasma.
No clinical signs of Pb toxicity were observed. Of all immunotoxicity tests, only TLR-3 was different (increased) in the highest exposure group. Mortality after bacterial challenge was lowest in the high exposure group (27.8%) compared to the low dose and control (55.5%) groups, showing a hormetic (immunostimulatory) effect with Pb exposed birds having better survival.
In contrast, malathion was immunosuppressive; mortality after E. coli challenge was higher in the high exposure group (50.0%) compared to the controls (22.2%). Of immunotoxicity tests, only humoral immunity was suppressed ($p<0.05$) in the higher malathion group. Histopathology revealed atrophy of the bursa of Fabricius, explaining the suppressed antibody response.
No clinical signs of PFOA toxicity were seen, morbidity after bacterial challenge was not different among the groups. The T cell response was lower ($p\leq0.02$) in PFOA exposed birds compared to controls. The B cell and innate immune responses were not different, but both T4 and T3 were lower in the PFOA exposed birds.
This work provides evidence that testing integrated immunity using an infectious challenge is a better predictor of immunotoxicity from exposure to environmental contaminants, than individual responses to immunotoxicity tests, and that biological responses are contaminant specific.

**ET10B-2**

**Comparative toxicity and risk evaluation of the anticoagulant rodenticide diphacinone in various species of birds**

A Rattner[1], KE Horak[2], KM Eisenreich[1], RS Lazarus[1], JD Eisemann[2], JJ Johnston[3]
[1]Patuxent Wildlife Research Center, USGS, BELTSVILLE, MARYLAND, United States of America
[2]National Wildlife Research Center, USDA, FORT COLLINS, COLORADO, United States of America
[3]Food Safety and Inspection Service, USDA, FORT COLLINS, COLORADO, United States of America

Several rodenticides have been identified as hazards to predatory and scavenging birds on a worldwide scale. In 2008, the US EPA imposed sales restrictions on second generation anticoagulant rodenticide active ingredients (brodifacoum, difethialone, bromadiolone, difenacoum), in part due to their persistence in biota. The action may be offset by expanded use of other rodenticides, including diphacinone (DPN). Based upon sublethal responses (prothrombin and Russell's Viper venom times) and lethality, American kestrels (Falco sparverius) were found to be 10 to 30 times more sensitive to an acute oral dose of DPN than Northern bobwhite (Colinus virginianus) and mallards (Anas platyrhynchos). The time course of coagulopathy following DPN administration is delayed, and does not necessarily correspond with maximal tissue residue concentrations. A companion acute toxicity study in Eastern screech owls (Megascops asio) was inconclusive as ~50% of the oral dose was regurgitated. The quantity of DPN retained by owls was estimated to range between 130 to 717 mg/kg, yet signs of toxicity (external bruising, internal hemorrhage, frank bleeding, and lethality) failed to yield a dose-response relationship. A pilot dietary study was undertaken in which DPN mixed into Nebraska Bird of Prey diet (2.5 and 10 ppm) was fed to owls for 7 days. Overt signs of toxicity and prolonged clotting time were observed at remarkably low dietary levels of DPN (estimated daily dose ranging from 50 to 200 µg), and a more definitive feeding trial is being undertaken. A risk evaluation of these and other exposure and effects data (Savarie et al. 1979; Johnston et al. 2005; Eisemann and Swift 2006) suggest that some raptors may be at risk of sublethal DPN exposure. In view of the paucity of threshold effect data following repeated daily exposure for birds of prey, additional DPN feeding trials with captive raptors and a refined risk analysis are warranted to better characterize the risk of secondary poisoning.

**ET10B-3**

**Neuroanatomical and behavioural effects of early exposure to BDE-99 in an integrated avian laboratory and field model system**

L Eng[1], TD Williams[1], SA Macdougall-Shackleton[2], RJ Letcher[3], JE Elliott[3]
[1]Simon Fraser University, BURNABY, Canada
[2]University of Western Ontario, LONDON, Canada
[3]Environment Canada, OTTAWA, Canada

Polybrominated diphenyl ethers (PBDEs) are a class of brominated flame retardants that have become ubiquitous in the environment. BDE-99 is one of the most abundant congeners, and is consistently found in avian tissue and egg samples throughout the world. Previous avian studies have shown that early developmental conditions, such as nutrition and contaminant exposure, can have long-term neuroanatomical effects on the song control system, which could in turn affect mating behavior and reproductive success. Avian brain structures that underlie song learning and production develop primarily in the first few months post-hatch, which makes their development particularly sensitive to conditions during the nesting period. The objective of this study was to determine neuroanatomical and behavioral effects of early exposure to BDE-99 in an integrated avian laboratory and field model system, using the Zebra Finch (*Taeniopygia guttata*) and the European starling (*Sternus vulgaris*) as model passerine species. The zebra finch is a useful model to monitor effects of contaminants under controlled laboratory conditions, as they reach sexual maturity within 90 days, and readily breed in captivity. The European starling can be used as an ecological equivalent for comparative *in situ* investigations. Starlings are widespread, readily use nest boxes, feed on terrestrial invertebrates, and are easy to sample. In both species, we exposed young for the duration of the nesting cycle to environmentally relevant, sublethal levels of BDE99 (0-250 ng/g bw/day). A preliminary study dosing zebra finch chicks with BDE99 for 21-days during the nestling phase showed that there was a strong dose-dependent relationship for plasma BDE99 levels at 30 days of age. Following dosing, we raised young to sexual maturity. In the zebra finches we assessed male mating behavior and song quality. We then collected the brains from both the zebra finches and the starlings, and measured the song control nuclei to determine whether early developmental stress in the form of exposure to PBDE-99 resulted in impaired development of the song-control system. In the zebra finches, we found no significant effect on the volumes of the song control nuclei. There were negative effects on singing behavior, but not song quality. We also observed negative effects on mating behavior and success. Measurement of starling neuroanatomy is currently underway.

**ET10B-4**

**Changes in retinol and thyroid function of peregrine falcon (Falco peregrinus) nestlings relative to brominated flame retardants and other contaminants**

J Fernie[1], RJ Letcher[2], M Alaee[1], L Champoux[2], S Brimble[1], V Palace[3]
[1]Enivronment Canada, BURLINGTON, Canada
[2]Environment Canada, OTTAWA, Canada
[3]Dept of Fisheries and Oceans, WINNIPEG, Canada

Many additive brominated flame retardants (BFRs) and historical contaminants (e.g., polychlorinated biphenyls PCBs) are lipophilic, persistent and bioaccumulative, and increasing, including in peregrine falcons. The exposure of wild birds to these chemicals is of concern since such exposure can alter thyroid hormone homeostasis, retinol and thereby potentially development and reproductive success. The objective of this study was to assess potential changes in circulating retinol and thyroid hormones in nestling peregrine falcons relative to contaminant concentrations previously reported. Blood samples were collected from 28-d old nestling peregrine falcons at active nests in urban or remote areas of the Canadian Great Lakes Basin. Urban nestlings were heavier than those from remote regions. Consistent with being heavier, female and male chicks had higher retinol concentrations in urban nests than remote nests and male nestlings had higher circulating triodothyronine (T3) levels. In the male peregrines from the remote nests, there appeared to be a slower conversion of thyroxine to T3. PBDE congeners and metabolites were negatively associated with bone length in these nestlings, and for the male peregrine chicks, there were significantly negative correlations between circulating concentrations of retinol and the major PBDE congeners, ΣPBDEs and ΣPCBs, with ΣPCBs and ΣOH-PCBs negatively correlated with circulating T3 levels.

**ET10B-5**

**CYP1A1 and CYP2B expression in mysticete skin biopsies from the Gulf of California: responses to contaminant or interspecies differences in detoxification ability?**

CM Fossi[1], J Urban[2], S Maltese[1], D Coppola[1], C Panti[3], L Rojas-Bracho[4], B Jimenez[5], J Muñoz-Arnanz[5], L Marsili[1]
[1]University of Siena, SIENA, Italy
[2]2Departamento de Biología Marina, Universidad Autónoma de Baja California Sur, LA PAZ, Mexico
[3]Department of Evolutionary Biology, University of Siena, Via A. Moro 2,, SIENA, Italy
[4]4Programa de Mammifero Marino - Instituto Nacional de Ecologia, C/o CICESE, ENSENADA, Mexico
[5]5Institute of Organic Chemistry, CSIC, Juan de la Cierva 3, MADRID, Spain

The main objective of this project was to investigate the inter-species differences in CYP1A1 and CYP2B expression and contaminant levels (OCs, PBDEs and PAHs) in three mysticete species, blue whale (Balaenoptera musculus), fin whale (Balaenoptera physalus) and Bryde's whale (Balaenoptera edeni) of Gulf of California (Mexico) using skin biopsy as diagnostic tools. A suite of sensitive non-lethal biomarkers was applied, for the first time, to the three mysticete species in order to evaluate the toxicological status of this cetacean species in the Gulf of California and also to explore the role of migratory behavior and the feeding habits (zooplankton-eating species fin whale and blue whale, fish-eating species Bryde's whale) in the evolutionary process of the two isoforms of CYP. This "multi-trial diagnostic tool", applied to skin biopsies, underlined differences in POP levels and molecular biomarker responses between the three mysticete species of Gulf of California. Two main factors seem to regulate the expression of different CYP isoforms in the three species studied: the inductive ability of POPs and the different evolution of the two cytochromes related to the different feeding habits of the mysticete species.
With regard to the level of POPs higher levels of DDTs and PCBs were detected in the zooplankton-eating species (fin whale and blue whale) in comparison to the fish-eating species (Bryde's whale). Particular concern can be generate by the high levels of PCBs detected to the migratory specie blue whale, that could bioaccumulate POPs while moving along the Californian coast. This contamination phenomena can have generate induction of both CYP1A1 and CYP2B in this species. On the opposite, extremely high level of both CYP1A1 and CYP2B were detected in the fish-eating species, showing similar level to odontocete species. Lower levels of OCs and high level of the CYP2B were detected in the Bryde's whale specimens, suggesting a higher detoxification ability in the fish-eating species. In conclusion these data indicate that two main factors can regulate the expression of the two CYP proteins in the mysticete species of Gulf of California: a) the inductive phenomenon linked to the presence of both planar (CYP1A1) and globular (CYP2B) POPs of in the blubber of blue whale; b) the role of evolutionary pressures related to the different dietary habits of the species (zooplankton-eating species fin whale and blue whale, fish-eating species Bryde's whale).

**Glutathione-s-transferase protein and activity in epidermal tissue of humpback whales**

M Burkard[1], W Huston[2], C Waugh[3], S Bengtson Nash[1]
[1]Griffith University, BRISBANE, Australia
[2]Queensland University of Technology (QUT), BRISBANE, Australia
[3]The University of Queensland, BRISBANE, Australia

Cetaceans (whales dolphins and porpoises) are particularly susceptible to accumulation of toxic burdens of lipophilic organochlorine compounds (OCs) due to their longevity and position at the top of marine food chains. Despite frequently reported elevated levels of blubber OC burdens in these species, the performance of chemical risk assessments is precluded by a lack of anciliary individual and toxicological information. Recently the International Whaling Commission (IWC) steering group on contaminants flagged the importance of driving research towards facilitation of cetacean chemical risk assessment.1

Currently OC toxicology on mysticetes (filter-feeding whales) relies primarily on skin and blubber biopsies due to the rarity of stranding events of these large, often migratory species. As such advancements in mysticete toxicology must be underpinned by utilisation of these tissues for further molecular assessments.
Glutathione-s-tranferase (GST) catalyses the conjugation of glutathione with various xenobitics and therefore plays a major role in preventing oxidative stress2. GST has been detected across the animal kingdom and like many detoxification enzymes is substrate inducible and therefore a potential candidate for biomarker applications. To date no studies have reported the presence of GST in the skin, the most accessible tissue, of cetaceans.
This study verified the presence of GST protein in the skin of humpback whales. Subsequently, GST activity was measured in skin extracts of 33 individual animals. No significant differences in activity were observed between sexes or between northward (post summer feeding) vs. southward (fasted) migration cohorts, although expressed activity was observed to be lower in southward migrating cohorts of both sexes. This is in contrast to the expected increase in lipophilic OC exposure occuring at this time due to remobilisation of contaminant burdens along with lipid reserves. The production of reactive oxygen species is however a consequence of all metabolic processes and it is possible that at this late stage of the migration, following extended fasting, metabolism has been significantly depressed masking the expected increase in lipophilic contaminant exposure. Future work will investigate the relationship between activity and organochlorine (OC) contaminant burdens of the whales to further assess the suitability of the enzyme as a biomarker of OC exposure.

## ET11 - Mechanistic modelling for risk assessment: sub-lethal responses and population-level effects

**ET11A-1**

**A matter of trust - stakeholders' perspectives on ecological modelling**

AD Hunka[1], A Thit[1], A Palmqvist[1], P Thorbek[2], VE Forbes[1]
[1]Roskilde University, ROSKILDE, Denmark
[2]Syngenta Jealot's Hill International Research Centre, BRACKNELL, United Kingdom
Ecological models are gaining momentum and popularity in ecological risk assessment. While the voices of critics seem to balance those of enthusiasts, we have decided to have a closer look at the role of models in an institutional context. Using the policy arrangements framework we have studied perspectives of three stakeholder groups on ecological modelling. 38 in-depth, semi-structured interviews were conducted so far, with stakeholders from regulatory authorities, pesticide producers and academia all over Europe. Confidential interviews comprised 15 open-ended questions, and were focused on the use of ecological models and recent changes in guidance documents and legislation.
The key informant approach was employed in recruiting our participants. They were first identified as key stakeholders in ecological risk assessment of pesticides and then sampled by means of a purposive (snowball) sampling, where each stakeholder indentified as important by others was interviewed and asked to suggest another key stakeholder for our study.
Results show that participants, although having different institutional backgrounds often presented similar perspectives and concerns about ecological modelling. The analysis of repeating ideas and keywords reveals that all stakeholders expect and require a lot from ecological models. Models are a complex matter for which communication and understanding are necessary.
It seems promising that all three groups see ecological models integrated in future environmental risk assessment, although some of the stakeholders are sceptical. Main hopes associated with models were to reduce the amount of expensive and complex testing and field monitoring, both at the product development stage and as an aid to mitigation measures. The analysis suggests that the needs of different stakeholders often overlap and thus that there is a good chance that consensus on the role and requirements of ecological modelling for risk assessment can be reached.

**ET11A-2**

**Scientific needs of regulators to implement ecological modelling in environmental risk assessment of pesticides**

S Duquesne[1], L Wendt-Rasch[2], G Ericsson[2], J Wogram[1]
[1]Umweltbundesamt, DESSAU, Germany
[2]Swedish Chemicals Agency, SUNDBYBERG, Sweden
With higher tier studies, the level of uncertainty in the environmental risk assessment of pesticides is reduced. However, such studies have also their limitations especially because of the limited number of scenarios tested. In this respect, ecological modelling could become a valuable complementary tool for risk assessors. But from the regulatory point of view, the implementation of models into the risk assessment of pesticides depends on a number of scientific considerations: (1) Models should include - or in some cases at least account for - various ecological, ecotoxicological and environmental parameters that influence the effects and processes of recovery (i.e., choice of relevant model species; density dependence processes and population regulation; interspecific competition and predation; sublethal, long-term and delayed effects of toxicants; abiotic parameters (e.g., temperature, pH); spatio- temporal scales and landscape dimension) (2) Models should be useful to assess problems of mixture toxicity and of repeated applications (3) Models should be validated using field information from monitoring data and post-registration studies corresponding to various scenarios of exposure.
Irrespective of the anticipated benefits of ecological models for the risk assessment, outcomes from traditional risk assessment will remain central in the decision making processes, in the case of pesticides which - under their conditions of use - have a potential of causing adverse effects on ecologically vulnerable species.

**ET11A-3**

**Bringing mechanistic modelling down to earth**

LW Barnthouse
LWB Environmental Services, HAMILTON, OH, United States of America
Ecologists have been developing mechanistic models of ecological systems ever since the 1960s, when computers capable of numerically solving complex sets of equations first became widely available. Within a few years it became clear that the ability of modelers to write equations and define parameters greatly exceeded the ability of empirical ecologists to measure parameter values and perform experiments needed to validate the models. With the technological tools available to today's ecological modelers, biological processes from the scale of the cell to the scale of an entire landscape can be linked together in a single model. However, the fundamental limitations on ecological modeling that were recognized 40 years ago still remain, and are even more important now than they were at that time. The purpose of this paper is to discuss those limitations, and propose steps that could be taken by today's ecological modelers to ensure that mechanistic models achieve their full potential in ecological risk assessment.
Two types of limitations are involved: process limitations and implementation limitations. The process limitations relate to the fact that the fundamental goals of ecological modeling - realistic representation of ecological processes, precise forecasting of future outcomes, and general applicability to a variety of situations, conflict with each other and cannot be simultaneously achieved. The implementation limitations relate to the difficulty of implementing complex models within regulatory decision-making frameworks.
This paper will illustrate the above limitations through illustrative case studies of past modeling efforts and regulatory applications. The case studies will include theoretical explorations of the tradeoffs between various types of uncertainties affecting ecological models and applications of models to two important environmental problems: assessing impacts of nuclear power plants on fish populations and predicting potential ecological effects of toxic chemicals. Based on these case studies, the paper will describe a generalized approach for ensuring that mechanistic models developed to support ecological risk assessments are not only properly tested and documented, but also suitable for implementation in regulatory applications such as pesticide registration and chemical risk management.

**ET11A-4**

**Using ecological modelling to link ecotoxicological data with protection goals: an industry perspective**

P Thorbek, P Edwards, R Murfitt, J Davies, R Brain, P Sweeney, I Sims, P Hendley
Syngenta, BRACKNELL, United Kingdom
The European Food Safety Authority (EFSA) recently published an opinion about protection goals, which was based on the ecosystems services concept. In the opinion, it was stated that for most ecosystem services the protection goal is at the population (or higher) level of organisation (although for vertebrates the protection goals may remain at the individual level for cultural reasons). The standard ecotoxicity data requirements for pesticide registration are, however, mainly focused at the level of individuals. Ecological modelling can make use of the standard data to assess the potential risks that exposure to pesticides may present to populations or higher levels of organisation and is compatible with current regulation. Here we propose a tiered system for how ecological modelling can bridge the gap between data at the level of individuals and the protection goals. We then we present three examples of how different types of ecological modelling have been used to refine ecological risk assessments for different pesticides. The first example demonstrates how a simple worst case toxicokinetic modelling based on field feeding rates can help refine risk assessments for birds. The second example shows how an individual-based population model was used to assess what impacts a pesticide might have on populations of non-target arthropods. The third example illustrates how ecosystem models can be used to assess the risk of indirect effects on aquatic ecosystems. The three examples presented here demonstrate how such models can help to refine risk assessments and extend the use of standard data to improve risk assessments.

**ET11A-5**

**Population viability analysis for determination of lethal and sublethal effects of pollutants on populations**

D Stark
Washington State University, PUYALLUP, WASHINGTON, United States of America
Matrix population models are some of the most widely used models by population biologists. They are easy to construct and understand, but are they a good choice for use by ecological risk assessment of chemicals? Here, I discuss the strengths and weaknesses of matrix models as a tool for ecological risk assessment using models developed for a number of organisms exposed to pesticides. Results of this study indicate that matrix models are a good choice for an initial screening of toxicant effects because multiple effects (lethal and sublethal) can be easily incorporated into these models, they are easy to develop, use, and to understand. Therefore, matrix models should be the first choice for an initial risk assessment.

**ET11A-6**

**Gaining insight in the interaction of zinc and population density with a combined Dynamic Energy Budget- and population model**

C Klok
IMARES, DEN HELDER, The Netherlands
Laboratory tests are typically conducted under optimal conditions testing the single effect of a toxicant. In the field, due to suboptimal conditions, density dependence can both diminish and enhance effects of toxicants on populations. A review of the literature by Forbes et al. (2001) indicated that general insight on interaction of density and toxicants is lacking, and therefore no predictions on their combined action can be made.
To investigate how density dependence interacts with toxicants one can conduct experiments at the population level and test the joint effect of density and toxicant concentration. Such a study, however, does not give insight in the mechanisms of interaction, and is not feasible for long-lived species. Another strategy is to test the combined effects of toxicants and population density on the demographic rates; survival, growth and reproduction of individuals in a bioassay and extrapolate these effects with population models to assess the impact on population viability. Changes in demographic rates result from changes in the energy budget of an individual. An energy budget model combined with a population model, therefore, is very useful to integrate effects of toxicants and density at the population level. This approach is exemplified by assessing the combined influence of zinc and population density on the population viability of the earthworm Lumbricus rubellus.

**ET11B-1**

**Comparison of bioassays with different exposure patterns: the predictive potential of mechanistic modelling**

E Billoir[1], H Delhaye[2], C Forfait[3], B Clément[2], S Charles[3], ML Delignette-Muller[3]
[1]Pôle de Recherche ROVALTAIN en Toxicologie Environnementale et Ecotoxicologie, VALENCE CEDEX 9, France
[2]Université de Lyon; ENTPE; LSE, VAULX-EN-VELIN, France
[3]Université de Lyon; Université Lyon 1; CNRS, UMR5558 LBBE, VILLEURBANNE, France
Static and flow-through experiments were carried out to test the effects of cadmium on laboratory aquatic microcosms. Our objective was to compare these two experiments characterized by different exposure patterns, time-varying and constant, respectively. Focusing on *Daphnia magna* survival, reproduction and growth, we addressed the questions of organism fitness and sensitivity to cadmium. For this purpose, a classical analysis of data (hypothesis testing, determination of No Observed Effect Concentrations and Effective Concentrations) provided poor information. As a modeling framework, dynamic effect models were built for the three life history traits we

considered (survival, growth and reproduction), accounting for daphnid responses to cadmium exposure through threshold stress functions. These models took the exposure pattern into account, making comparable the results obtained from our two experiments. Contrary to the classical analysis, this modeling framework enabled us to detect an improvement of organism development in flow-through conditions compared to static ones and infer similar sensitivity to cadmium in both exposure patterns.

**ET11B-2**

**Juvenile food limitation: ecotoxicologists, be warned!**

EI Zimmer[1], J Jager[1], V Ducrot[2]
[1]Vrije Universiteit Amsterdam, AMSTERDAM, The Netherlands
[2]INRA, RENNES, France

It is in the nature of standard ecotoxicological tests that they are as simple as possible. They are generally conducted under standardised laboratory conditions for the species of interest; conditions which have been proven to maintain the species in a good condition. However, what does good condition mean? Since we do not know exactly what the organisms eat in their natural habitat, and some even change their diet during the life-cycle, it is likely that the chosen food is not optimal for them throughout the whole life-cycle. If we do not know exactly what situations we investigate in the laboratory toxicity tests, how can we trust our extrapolations to populations in the field?

For ecological risk assessment, it is essential to detect only effects that are caused by the chemical of interest, and to exclude any side effects following from experimental conditions. Under food limitation, organisms are stressed, and respond differently to toxicant exposure. Therefore, it is important to closely investigate the organism's food requirements: if the test organisms are stressed due to food limitation, this stress might interact with the effect of the chemical, and lead to an overestimation of the chemical's toxicity. Diagnosing food problems and predicting the interactions between food and toxicants requires a mechanistic modelling framework that explains how food is used to fuel the life-history traits, and how toxicants affect this process. We demonstrate that Dynamic Energy Budget (DEB) theory is very well suited for this purpose.

Lymnaea stagnalis, the great pond snail, has recently been proposed as a good candidate species for developing OECD guidelines devoted to the risk assessment of endocrine disrupting components. Analysing life-cycle data from L. stagnalis, we detected food limitation in the early juvenile stage under controlled laboratory conditions. In a simulation study with the DEB model, we investigated how an initial food limitation in juveniles affects the interpretation of toxicity data, and distorts the extrapolation of toxic effects to the population level.

**ET11B-3**

**The importance of density dependence and intra-specific interactions in population models for use in ecological risk assessment**

RE Hazlerigg[1], K Lorenzen[1], CR Tyler[2], JR Wheeler[3], P Thorbek[3]
[1]Imperial College London, ASCOT, United Kingdom
[2]University of Exeter, EXETER, United Kingdom
[3]Syngenta Ltd., BRACKNELL, United Kingdom

The range of endpoints used to assess the effects of test substances in the laboratory cover mortality, growth and development. However, population level processes (e.g. density dependence, behavioural interactions) may mean that statistically significant effects from laboratory based studies may not necessarily reflect their real-world importance for population abundance and biomass. We have formulated an individual-based zebrafish population model using results derived from a survey of wild fish, semi-natural experiments and meta-analysis data. The model, written in Netlogo (CCL, Northwestern University), mimics a 6m square pond. Zebrafish development is divided into four life-stages (eggs, larvae, juveniles and adults) with life history characteristics altered with each time-step. Density dependence is included for growth and survival and parameterised from experimental results. Exposure scenarios causing a 10, 50 and 90% decrease in growth rate and fecundity were investigated. Sex ratio scenarios tested for a 10, 30, 70 and 90% proportion of the population developing into males. Each simulation ran for 3000 days, with each scenario repeated 10 times. Growth depression resulted in significantly reduced abundance of mature females (K-W, DF = 3, $P < 0.001$). A 50+% decrease in growth rate resulted in population extinction within the 3000 day simulation. Fecundity depression resulted in significantly increased abundance of mature females in the population (ANOVA F3, 36 = 16.93, $P < 0.001$), likely caused by increased young survival through density dependent processes at lower population densities. Sex ratio changes in the hatched eggs resulted in altered sex ratios in the mature population. However, the abundance of mature adults in the population significantly increased with increasing male sex ratio bias (ANOVA F3, 36 = 9.46, $P < 0.001$), likely caused by the earlier maturation of male individuals compared with female individuals. In conclusion, firstly, populations are sensitive to changes in the growth rate of individuals, with small reductions in individual growth rates resulting in large reductions in population abundance. Secondly, fecundity reductions often observed via endocrine mediated effects may be compensated for in wild populations due to density dependent processes. Thirdly, although feminisation of fish by endocrine disruptors is commonly found, sex ratio bias is not necessarily a cause for concern at the population level in its own right.

**ET11B-4**

**An agent-based model of woodpigeon populations and its use for risk assessment.**

KA Matuszewska, TM Kulakowski, RM Sibly
University of Reading, READING, United Kingdom

European regulations concerning pesticide risk assessment focus on the protection of populations [1,2]. However, field experiments to measure this risk are expensive, logistically challenging and involve extensive animal experimentation. Population modelling seems to be one of the best ways of extrapolating to the population scale from individually measured effects and data on the behavioural ecology of the species at risk. Agent-based models (ABMs) that incorporate effects of intraspecies variation and landscape use can minimise the need for animal testing in higher tier risk assessment. In ABMs each individual animal can be modelled separately, and, in contrast to standard population models, we do not need to guesstimate the values of parameters describing population dynamics. Instead the population dynamics emerges from the system in a way that depends on the input parameters describing individuals and their modelled behaviour.

We have developed an ABM of woodpigeon population that can be used for risk assessment of new pesticides. Woodpigeons were chosen because they are an exceptionally vulnerable species, a consequence of their mostly herbivorous diet which is mainly gathered in agricultural terrain. They feed extensively on oilseed rape, sown cereals and leafy vegetables. In the past there have been incidents of woodpigeons poisoning ascribed to pesticide use.

In the model we included life history traits, mating and reproductive behaviour and winter flock formation to simulate the annual cycle of the birds. The rules of daily choice of feeding grounds and type of preferably collected food were also specified. We included the possibility of pesticide application and so can compute its effects on the woodpigeon population. The emergent properties of the model are statistics describing the population dynamics, including population size, growth rate and recovery time after disturbance.

The results from the model have been compared to the observations gathered during the long-term woodpigeon study in Carlton, Cambridgeshire, UK [3].

**Towards good modelling practice: TRACE, a standard for documenting ecological modelling in chemical risk assessment**

V Grimm[1], A Schmolke[1], DL Deangelis[2], P Thorbek[3]
[1]Helmholtz Centre for Environmental Research - UFZ, LEIPZIG, Germany
[2]USGS/Florida Integrated Science Centers and University of Miami, CORAL GABLES, United States of America
[3]Syngenta, Environmental Safety Jealott's Hill Research Centre, BRACKNELL, United Kingdom

Ecological models are becoming increasingly important in the context of chemical risk assessments. Due to the interaction of numerous factors, and the extent of temporal and spatial scales of concern, empirical approaches often are too limited to inform decisions or regulations that are aimed at the population or ecosystem level. Ecological models have the potential to bridge this gap. However, no general guidelines exist for the development and use of ecological models. Such guidelines for good modelling practice would be essential for quality assurance of ecological models in the context of chemical risk assessments, and would provide a tool for regulatory agencies to assess the usefulness of models in specific contexts. We present the first step towards the implementation of a good modelling practice: TRACE, a standard framework for the documentation of ecological models and the underlying modelling process. TRACE covers model development, evaluation, and application. By providing a document that applies the proposed framework, modelling projects become transparent, and decision makers as well as potential peer reviewers can assess the quality and usefulness of a model for the problem at hand. Thus, the proposed model documentation framework is the basis for the compilation of an actual guideline for good modelling practice in risk assessment contexts. Using example models, we will demonstrate how TRACE documents are compiled and evaluated.

**Key role of the resin thickness on the metal flux and lability degree of complexes measured with diffusion gradients in thin films (DGT)**

J Puy[1], S Mongin[1], R Uribe[1], J Cecilia[1], J Galceran[1], H Zhang[2], W Davison[2]
[1]Lleida University, LLEIDA, Spain
[2]Lancaster University, LANCASTER, United Kingdom

Diffusion gradients in thin film devices (DGT) (1-3) has emerged as a powerful technique for in situ measurement of metal fluxes. It consists in a resin layer that strongly binds the metal ions, covered with a gel layer that defines a diffusion domain.

Metal accumulation in DGT devices depends on both the free metal present in the system and the complexes able to dissociate in the time scale of the experiment. A quantitative measure of the complex contribution is the lability degree.

As penetration of complexes into the resin layer is a characteristic feature of the DGT devices, expressions reported for the lability of complexes in voltammetric sensors (4) are, in general, not applicable to DGT

The binding of the free metal by the resin in the resin layer expands the effective reaction layer, i. e., the layer where there is net dissociation. This extension leads to an important increase of both the metal flux and the lability degree in comparison to the values expected when complexes are not able to penetrate into the resin phase. Experimental results of the Cd NTA system confirm these findings.

The limiting case (where metal concentration in the resin layer is negligible) is used to obtain analytical expression for the metal flux and lability degree. From these expressions, the impact of resin and gel thickness, kinetic constants, diffusion coefficients on the DGT response will be discussed, as well as the environmental consequences.

**Development of a reliable and robust method for the detection of ng/L concentrations of Lipid - Soluble Metal Complexes in natural waters**

DA Kilgore[1], S Apte[2], G Hose[3], M Taylor[3]
[1]Macquarie University and CSIRO, CRONULLA, Australia
[2]CSIRO Land and Water, LUCAS HEIGHTS, Australia
[3]Macquarie University, NORTH RYDE, Australia

In natural waters trace metals are present in a wide range of physico - chemical forms or species.

It has been demonstrated that the toxicity of these trace metals to aquatic organisms is related in many cases to the activity of the free metal ion species. However, several studies have shown that the toxicity and bioavailability of Lipid - Soluble Metal Complexes (LSMC), formed by the reaction of metals with synthetic and natural organic ligands, may exceed that of the free metal ion. Surprisingly, there have been very few studies conducted that seek to identify and quantify LSMC in aquatic systems. This is mainly due to the fact that a reliable, robust and sensitive method for the determination of LSMC in waters has not yet been developed. In this research, a sensitive method for the determination of ng/L concentrations of lipid soluble cadmium, copper, nickel, lead and zinc complexes in waters was developed. Waters were extracted under clean room conditions using dialysis cells containing 1-octanol. The metals were then preconcentrated by vacuum distillation, back-extracted into nitric acid and determination and quantified was performed by Inductively Coupled Plasma Mass Spectrometry. By using dialysis membrane the water and solvent are physically separated ensuring the solvent does not become contaminated with colloid material which may positively bias the results. The pore size of the dialysis membrane still allows for the diffusion of LSMC into the solvent. Detection limits for the method were in the low ng/L allowing the developed method to be used to determine the concentrations of LSMC in a range of aquatic environments.

**ET12A-3**

**Effect of organic complexation on copper accumulation and toxicity to the estuarine red macroalga Ceramium tenuicorne: a test of the free ion activity model**

EP Ytreberg, B Eklund, K Ndungu
Stockholm University, STOCKHOLM, Sweden

Current water quality criteria (WQC) regulations on copper toxicity to biota are still based on total dissolved (< 0.4 micron membrane filter) copper concentrations with a hardness modification for freshwaters. There are however ongoing efforts to incorporate metal speciation in WQC and toxicity regulations (such as the biotic ligand model-BLM) for copper and other metals. Here, we show that copper accumulation and growth inhibition of the Baltic macroalga *Ceramium tenuicorne* exposed to copper in artificial seawater at typical coastal and estuarine DOC concentrations (similar to 2-4 mg/L-C as fulvic acid), are better correlated to weakly complexed and total dissolved copper concentrations rather, than the free copper concentration [Cu2+]. Our results using a combination of competitive ligand exchange-adsorptive cathodic stripping voltammetry (CLE-ACSV) measurements and model calculations (using visual MINTEQ incorporating the Stockholm Humic Model) show that copper accumulation in *C. tenuicorne* only correlates linearly well to [Cu2+] at relatively high [Cu2+] and in the absence of fulvic acid. Thus the FIAM fails to describe copper accumulation in *C. tenuicorne* at copper and DOC concentrations typical of most marine waters. These results seem to indicate that at ambient total dissolved copper concentration in coastal and estuarine waters, *C. tenuicorne* might be able to access a sizeable fraction of organically-complexed copper when free copper concentration to the cell membrane is diffusion limited.

**ET12A-4**

**Toxicity of metal mixtures to Daphnia magna: a test of a multi-metal, multi-site biotic ligand model using Cu and Zn**

JS Meyer[1], JF Ranville[2], M Pontasch[2], RC Santore[3], JW Gorsuch[4], WJ Adams[5]
[1]ARCADIS, GOLDEN, CO, United States of America

[3]HydroQual, Inc., EAST SYRACUSE, NY, United States of America
[4]Copper Development Association, WEBSTER, NY, United States of America
[5]Rio Tinto, LAKE POINT, UT, United States of America

For decades, a simplistic summation of toxic units based on concentrations of dissolved metals has been used to semi-quantitatively predict the toxicity of metal mixtures. However, that approach tends to over-predict toxicity. In its place, we have been developing a mechanistic model based on tissue residues of metals and the concept that the toxicity of a mixture of metals can be either dose additive or response additive, depending on the mechanisms of action. To calculate tissue residues and thereby predict toxicity across wide ranges of water quality, we have been developing a multi-metal, multi-site biotic ligand model (MMMS BLM) that concurrently accounts for metal-metal competition for binding on dissolved ligands in the water and at sites of toxicity on organisms. In our initial tests, we exposed *Daphnia magna* to mixtures of Cu and Zn in moderately hard reconstituted water containing dissolved organic (DOC; added as Suwannee River fulvic acid) at 3 mg/L, and compared observed mortality to the response-additive mortality predicted from results of Cu-only and Zn-only toxicity tests. This research has revealed several apparent metal-metal interactions that otherwise might lead to conclusions that metals interact in non-additive ways, yet simple geochemical speciation in the BLM can explain these interactions and reconcile the apparent non-additive toxicity. For example, the toxicity of Cu-Zn mixtures always appeared to be synergistic or additive when based on dissolved metal concentrations, whether Cu was varied while Zn was held constant, or vice versa; whereas in the same tests, the toxicity of the Cu-Zn mixtures always appeared to be antagonistic or additive when based on free-metal-ion concentrations. These preliminary results demonstrate that a MMMS BLM could be an effective tool to help regulatory agencies implement more appropriate methods to regulate metal mixtures than the current default, overly conservative toxic-units approach.

**ET12A-5**

**Effects of chronic nickel exposure on algae, zooplankton and snails in a semi-realistic microcosm**

U Hommen[1], C Schäfers[1], H Rüdel[1], B Knopf[1], C Schlekat[2], E Rogevich[2]
[1]Fraunhofer IME, SCHMALLENBERG, Germany
[2]NIPERA, DURHAM, United States of America

Until now the aquatic risk assessment for Ni has been based on a large set of single species tests. In order to refine this assessment a microcosm study was performed to evaluate the impact of dissolved nickel on an aquatic community including phytoplankton, zooplankton, periphyton and snails. The study was conducted in 14 microcosms (including a natural sediment layer of 20 cm and an overlaying water volume of 750 L) located in a greenhouse at the Fraunhofer IME in Germany. After a pre-treatment period for establishing the populations, a Ni solution was added to reach concentrations of 6, 12, 24, 48 and 96 µg Ni/L in two microcosms each. Four microcosms served as untreated controls. To achieve constant exposure, appropriate amounts of nickel solution were added over the whole exposure period of 4 months, mostly on a daily basis. Ni concentrations were analytically determined frequently (at least weekly) in each microcosm over the 16 week exposure period. Parameters known to affect Ni toxicity, including water hardness, pH, and dissolved organic carbon (DOC), were also measured represented conditions of high bioavailability. Population and community level indexes were determined for phytoplankton, zooplankton, periphyton, and snails. No adverse effects for these endpoints were found at concentrations below 48 µg Ni/L. Only minor, inconsistent, and/or temporary deviations from controls, i.e., for single sampling dates, were found for a few taxa at concentrations below 48 µg Ni/L. However, these deviations were not related to clear dose-response relationships and not found at the end of the study. Considering the stable exposure over 4 months, these deviations are not seen as adverse effects of Ni exposure. In contrast to this, at 48 and 96 µg Ni/L long-term effects on phytoplankton, rotifers, snails and, due to reduced grazing by snails, indirectly on the periphyton biomass were observed. Thus, the overall NOEC for a 4 months exposure to nickel in this microcosm study is considered to be 24 µg Ni/L.

**Hazard assessment of inorganic selenium under REACH: a pragmatic approach**

K Oorts[1], NME Deleebeeck[2]
[1]ARCHE, GENT, Belgium
[2]ARCADIS Belgium, GENT, Belgium

Selenium is an essential element showing a very narrow margin between dietary essentiality and toxicity. So far, the main focus of the extensive research on selenium has been the environmental fate and effects of the element in the aquatic environment. The available scientific knowledge indicates that diet is the primary exposure pathway for both aquatic invertebrates and vertebrates and that selenium toxicity is primarily manifested as reproductive impairment in egg-laying vertebrates (fish and birds) due to maternal transfer. The severity of the observed adverse effects appears to be more related to tissue concentrations than to aquatic concentrations of the element and selenium toxicity seems to be largely species- and site-specific. Therefore, it is generally accepted that a single predicted no effect concentration (PNEC) based on aqueous Se concentrations would not be appropriate for protecting against selenium toxicity in all systems and that selenium requires site-specific risk assessment to a much greater extent than many other contaminants. However, the European REACH Regulation and other regulatory risk assessment methods traditionally require the derivation of a single threshold concentration of a substance for each environmental compartment (e.g. water, soil, sediment) based on toxicity data for the most sensitive species and ecosystem. For selenium, such an approach would entail the risk of defining PNEC values within the deficiency range for many systems. Since REACH and similar regulations are pushing the limits with regard to timely submission of chemical safety reports, they also force difficult substances such as selenium to be assessed in a pragmatic way using the scientific knowledge already available. A pragmatic approach for the aquatic and terrestrial hazard assessment of selenium under REACH will be presented and the potential for further refinement will be discussed.

**ET12B-2**

**Determination of free metal concentrations with AGNES-SCP**

D Aguilar[1], J Galceran[1], E Companys[1], J Puy[1], C Parat[2], L Authier[2], M Potin-Gautier[2]
[1]Universitat de Lleida, LLEIDA, Spain
[2]Université de Pau et des Pays de l'Adour, PAU, France

Gaining access to the free concentration of a variety of metals ions, such as Zn, Cd, Pb or Cu, is key to predict the role and fate of nutrients and pollutant elements in different natural environments like fresh water [1]. Consequently, there is a demand for methodologies that allow the direct quantification of metal ion concentrations under environmentally relevant conditions and at trace level. AGNES (Absence of Gradients and Nernstian Equilibrium Stripping) is an electroanalytical technique specifically designed for the determination of free ion concentrations with great environmental interest [2]. Consits of two stages: i) a deposition stage in a mercury amalgam, until equilibrium with the solution is reached; ii) a stripping stage where the element is quantified. Typically, AGNES has been applied with mercury electrodes (HMDE), but, recently, also with screen printed ones (SPE) which could allow to perform in situ measurements due to their small size [3]. In this work, we introduce Stripping Chornopotentiometry (SCP) as the second stage of the technique in order to better deal with possible interferences in complex samples. Suitable experimental conditions have been found for the successful application of the combination of AGNES and SCP both with HMDE and SPE. Calibrations with solutions containing Zn2+, Cd2+ and Pb2+, either alone or the three together, have been carried out satisfactorily. Moreover, speciation studies of Cd2+ in presence of Pb2+ confirm that AGNES-SCP allows to easily determine the free metal concentration in solutions containing interferents. Finally, this approach was tested on a fresh water sample from Garona river taken in Val d'Aran (Spain) and it could be possible to compute the free Zn2+ concentration which was around 30% of the total concentration.

**Life-cycle traits of Porcellio dilatatus exposed to different Cd species: effects on survival and reproduction**

CF Calhôa, AMV Soares, S Loureiro
CESAM & Department of Biology, AVEIRO, Portugal

The woodlouse *Porcellio dilatatus* (Crustacea) is a suitable model species for the examination of toxic effects following metal assimilation and accumulation. In this study, the influence of cadmium speciation in survival and reproduction of isopods was investigated. Survival and reproductive parameters (pregnancy and abortion occurrence, number of juveniles per female and juvenile weight) were recorded when isopods were exposed to two species of Cd deployed in food: $Cd(Cys)_2$ or $Cd(NO_3)_2$. There was a difference between survival rates of exposed males and females to both Cd species but in the case of $Cd(NO_3)_2$ these differences were more accentuated, with females having higher survival rates. In the presence of both metal species a reduction of pregnancies was observed, but in the case of $Cd(Cys)_2$ all pregnancies were inconclusive. The number of juveniles delivered per female fed with $Cd(NO_3)_2$ contaminated food was lower than in the control but the juvenile weights were higher. As far as we are aware, the present study is the first toxicity test demonstrating that metal speciation affects reproduction. $Cd(Cys)_2$ showed to be more toxic in this long term exposure and to jeopardize completely the reproduction effort of isopods.

### ET12B-4

**Solid-phase applications for biosensor deployment in predicting the biotoxicity of heavy metals in soils**

W Ma, GI Paton
Institue of Biological and Environmental Sciences, University of Aberdeen, ABERDEEN, United Kingdom

Assessment of bioavailability of contaminants in the environment is important in the context of hazard assessment and remediation. Traditionally, the pollutants have been assessed by using only chemical assays or evaluating physical parameters. To complement this, biosensing systems have been developed to integrate with traditional assays.
In recent years, reporter-gene constructed bacteria (biosensor) for specific pollutants have been successfully applied for heavy metals. The stress induced by toxic compounds can cause disruption to the metabolism of organisms. So once changes occur, it is essential to quantify this impact. In this study, the bioluminescent biosensors produces light which correlates with the dose present in presence of target analytes (Cu and Zn). Understanding the speciation of heavy metals and its relationship with biological responses is an important factor for the soil assessment.
So far, the application of microbial biosensors has relied solely on the extraction of pore water and the subsequent exposure to the test organisms. This fails to consider the complex environment of the soil solid phase which is likely to host most of the labile and bioavailable pollutants and be the more dynamic in both space and time to perturbations.
The deployment to soil will be likely to be coupled with an approach such as "rhizon sampler"where the solution will be extracted from the soil and then assimilated onto the solid phase extraction (SPE) surface. In this study, a range of novel solid phase devices were compared to assess the reproducibility of given assays and their relationship with aqueous phase assays.
In general, the toxicity and bioavailability of heavy metals in solid phase was lower than in aqueous phase demonstrating the need to measure both phases and develop a relationship between them and the likely mobility and partitioning of the target analytes.
Future research will consider the bioavailability of hydrocarbons and in addition to assessing its related toxicity. This will be further inferred to a reliable method of the potential for biodegradation and bioremediation.

### ET12B-5

**Plant toxicity of 5 years aged Pb salts in soil in relation to recent amendments**

K Cheyns[1], S Peeters[2], D Delcourt[2], E Smolders[2]
[1]KULeuven, HEVERLEE, Belgium
[2]Division soil and water management KULeuven, HEVERLEE, Belgium

Lead toxicity data derived from soils freshly spiked with Pb salts may overestimate Pb toxicity under field conditions because of a reduced mobility and lower soil solution ionic strength in field contaminated soils. This study was designed to quantify the difference in Pb toxicity between soils dosed with $Pb(NO_3)_2$ left to age 5 years outside with natural leaching, soils freshly dosed with PbCl2 and soils freshly dosed with $PbCl_2$ leached with artificial rainwater. Toxicity was assessed with plant growth (*Lycopersicon esculentum* L.). Leaching of the spiked soils resulted in significantly (p=0.05) higher EC50 values of Pb in soil compared with the EC50 values of Pb of the spiked but unleached soils. Lead in aged soils is still less toxic than in spiked + leached soils, suggesting that ageing does reduce toxicity. To extrapolate toxicity values obtained with laboratory spiked soils to field relevant situations a leaching/ageing factor is needed. This study explain that both processes contribute to the observed discrepancies.

### ET12B-6

**Trace metal fate and uptake by vegetables grown in close proximity to traffic in Toronto, Canada**

CLS Wiseman
University of Toronto, TORONTO, Canada

Existing knowledge regarding the processes regulating metal bioavailability under natural conditions and their uptake by plants has been identified as a primary limiting factor in the development of reliable soil quality guidelines. Much of the information about metal dynamics in soils, and the role of various physicochemical characteristics incorporated in more advanced fate models, has been derived from controlled lab studies, using artificially amended soils. Recent evidence suggests that metals present in field soils, which have undergone natural aging processes, are comparatively much less likely to be bioavailable. This highlights the need to further examine the effects of metal aging in soils under natural conditions to ensure that soil quality guidelines are more reflective of the risks trace metals pose in the urban environment.
This research examines the fate of traffic-related trace metal emissions and their uptake by plants grown in Toronto, Canada. Oregano (O. heracleoticum), eggplant (S. melongena) and beets (B. vulgaris) were cultivated at several locations with predicted variable metal inputs over the growing season in 2010. At one location, which is situated at a busy intersection on the St. George campus location of the University of Toronto, the top 30 cm of soil was replaced with an organic, triple mix soil. The same soil was used to cultivate plants in containers at the other two locations. In addition, oregano (O. heracleoticum) plants were planted at three other sites located close to several major roads, which have some of the highest traffic densities in Toronto (planted in existing soil). Preliminary results from the first phase of this study to examine trace element stabilization processes in aging field soils indicate a rapid accumulation of trace metals in newly remediated soils in close proximity to traffic (e.g. Mo, Cd, Pb, V, Cr, Co, Ni, Cu and Zn). At the same time, the rhizosphere soil of cultivated eggplant (S. melongena) has significantly lower trace metal concentrations compared to bulk soil measurements (e.g. Cd, Pb, Cr and V). The physicochemical differences in the bulk soil compared to the rhizosphere soil, and the associated differences in trace metal concentrations, require further attention in attempts to develop soil quality guidelines. Finally, soil contamination is clearly not restricted to urban areas, as is often assumed, but may be more a reflection of regional contaminant levels.

### ET12C-1

**Metals incorporation and physiological changes in Ulva spp. as responses to the nocturn pulse of metals from sediment in eutrophic systems - a field transplantation experiment**

P Pereira[1], H de Pablo[1], C Vale[1], M Pacheco[2]
[1]Instituto Nacional de Recursos Biológicos (INRB/IPIMAR), LISBOA, PORTUGAL, Portugal
[2]CESAM/Departamento de Biologia da Universidade de Aveiro, AVEIRO, Portugal

Coastal lagoons with symptoms of eutrophication often present low oxygenated waters, particularly during the night. Under such conditions, sediment could release metals to the overlying water. Consequently, inhabitant organisms may accumulate metals that were provided from the sediment, which could be on the basis of adaptative responses such as those related with the protection against oxidative stress. Keeping this in view, it is relevant to clarify if the macroalgae Ulva ssp. transplanted in short-time exposures (during 24 hours) respond to the increase of metal availability both in terms of metals accumulation and changes of its physiological status. A field transplantation experiment was performed with Ulva spp. in three short-time exposures (between 15:30-00:30; 00:30-07:30; 07:30-15:30) along a period of 24 hours in summer 2007. This study was carried out in a coastal lagoon previously considered to be a paradigm of eutrophic conditions and moderately contamination by metals (ð'bidos lagoon, Portugal). In summer, dissolved oxygen in a confined branch of the lagoon (Barrosa branch) could fluctuate pronouncedly along a day-night cycle. Ulva spp. was collected at a reference site and transplanted to Barrosa branch and a site near the reference (Lower lagoon) in order to evaluate the uptake of metals and oxidative stress effects. Water quality (including metal levels in water) was also characterised along the 24-hours cycle.
Dissolved oxygen at Barrosa branch varied between 40% and 190% saturation levels, being the most elevated values recorded at daylight hours and lower oxygenation during the night. Increase of ratios to Al of particulate Mn, Fe and Pb during the night revealed an additional enrichment of these elements in the suspended particulate matter. This enhancement pointed to a supplementary input of metals from the sediment occurring during the night. Ulva spp. translocated to the Barrosa branch incorporated significantly higher levels of metals in comparison to Lower lagoon, indicating that the algae respond within hours to the higher metal availability. An induction of SOD and an inhibition of CAT were recorded in Ulva spp. transplanted to Barrosa branch (between 0:30 and 7:30), eventually as a response to the higher incorporation of Mn, Fe and Pb. Ulva spp. incorporated metals and exhibited physiological changes within hours exposures, reflecting the pulse of metals from sediment during the night.

### ET12C-2

**Kinetics of mercury bioaccumulation in the polychaete Hediste diversicolor and in the bivalve Scrobicularia plana, through a dietary exposure pathway**

G Cardoso[1], E Pereira[2], TF Grilo[1], AC Duarte[2], MA Pardal[3]
[1]IMAR - Institute of Marine Research, COIMBRA, Portugal
[2]CESAM, AVEIRO, Portugal
[3]CEF, COIMBRA, Portugal

Mercury bioaccumulation kinetics of two important macrobenthic species, the polychaete Hediste diversicolor and the bivalve Scrobicularia plana were evaluated following a dietary pathway (i.e. contaminated algae), through a mesocosm laboratory experiment.
Both studied species presented a similar model of Hg bioaccumulation kinetics, a linear pattern of accumulation through time being the mercury accumulation in the organisms proportional to the mercury concentration in the food. Moreover, the mercury bioaccumulation rates were higher in the polychaete H. diversicolor than in the bivalve S. plana, which can be related to their feeding strategies, ingestion rates and assimilation efficiencies.
Comparing the effect of different exposure pathways (food versus sediment) on the mercury bioaccumulation rates, we may infer that mercury uptake via food (i.e. particulated macroalgae) is a major pathway of metal bioaccumulation for the polychaete H. diversicolor, while for the S. plana it seems to be the sediment. Moreover, the mercury bioaccumulation process through the dietary pathway, revealed to be faster than through sediment exposure, especially for the polychaete, which can represent a non-negligible risk for Humans.

### ET12C-3

**The impact of improved oxygen concentrations on the bioavailability, accumulation and toxicity of sediment-bound metals in freshwater invertebrates**

M de Jonge, J Teuchies, R Blust, L Bervoets
University of Antwerp, ANTWERPEN, Belgium

The present study evaluated the effect of improved oxygen concentrations in overlying surface water on the bioavailability, accumulation and toxicity of sediment-bound metals in the aquatic invertebrates *Lumbriculus variegatus* and *Asellus aquaticus*. A 60 days lab experiment with natural metal-polluted sediment containing high amounts of organic matter and AVS was conducted in 2 different experimental containers. At 6 different time points (after 0, 2, 5, 12, 32 and 54 days) the total metal content, Acid Volatile Sulfides (AVS) and organic matter was measured in the sediment. In addition the metal bioavailability in both water and sediment was measured using Diffusive Gradients in Thin films (DGT) and metal accumulation together with toxicity endpoints was analyzed in the invertebrate species. Our results indicated that $SEM_{Tot}$-AVS levels in the upper layer of the sediment (0-1 cm) significantly increased after exposure to elevated oxygen concentrations in the surface water. The glycogen content of the organisms in the high oxygen treatment did not significantly differ between the exposure dates and only after 54 days a significant difference in glycogen content between the treatments was noticed. Furthermore no significant correlations could be found between SEMTot-AVS in the sediment and the glycogen content in *Asellus aquaticus*. These results indicate that after almost 60 days of elevated oxygen concentrations in the surface water, metal release from the sediment has not increased enough to induce toxic effects in water-inhabiting invertebrates like *Asellus aquaticus*. Further work of this study will investigate the metal concentrations in DGT and the accumulation in the aquatic invertebrates in order to reveal to which extent metals can be mobilized and accumulated from sediment after increased oxygen exposure.

### ET12C-4

**Adaptation of copper community tolerance levels after transplantation of biofilms in an urban river**

LC Fechner[1], F Versace[1], C Gourlay-Francé[1], MH Tusseau-Vuillemin[2]
[1]Cemagref, ANTONY, France
[2]IFREMER, ISSY-LES-MOULINEAUX, France

The aim of this study is to investigate the adaptation of tolerance levels of biofilms transplanted either from a non-contaminated area to an urban-contaminated site or, conversely, from a contaminated area to a non-impacted site. For that purpose, natural fluvial biofilms were collected upstream the urban area of Paris (site A) and transplanted downstream from Paris (site B2), and conversely, biofilms were collected in the urban area of Paris (site B1) and transplanted upstream (site A). Cu tolerance levels of biofilms (both transplanted and original communities) were measured, using a previously developed short-term toxicity test based on the measure of beta-glucosidase activity, just before transplantation and then 15 and 30 days later. Automated-Ribosomal Intergenic Spacer Analysis (ARISA) was used to analyze similarities in both bacterial and eukaryotic community structures of the biofilms.

Biofilms' Cu tolerance levels varied significantly with transplantation: an increase of tolerance was measured for the biofilm TA transferred upstream (site A) to downstream (site B2) and a decrease of tolerance was measured for the biofilm TB1 transferred downstream (site B1) to upstream (site A). Moreover, ARISA fingerprints revealed that both bacterial and eukaryotic community structures were impacted by transplantation. Principal Component Analysis of ARISA profiles grouped upstream (A and TB1) communities on the one hand and downstream (TA and B1) communities on the other hand.
The study shows a fast adaptation of both Cu tolerance levels and community structure of biofilms subjected to a drastic change of environmental surroundings by transplantation.Therefore, transplantation has a predominant impact on periphyton both in terms of community structure and tolerance levels. This study confirms that tolerance measurements are sensitive indicators of metallic exposure levels.

**ET12C-5**

**Exploring genomes to understand how populations are shaped by the environment**

JR Shaw[1], S Paland[1], S Glaholt[1], M Pfrender[2], J Colbourne[1]
[1]Indiana University, BLOOMINGTON, IN, United States of America
[2]Notre Dame University, SOUTH BEND, IN, United States of America

Environmental genomics seeks to understand how gene function is influenced by environmental conditions while accounting for variation that exists within and among natural populations. We apply environmental genomics to link gene-environment interactions to the fitness of individuals and to population-level outcomes in natural populations of Daphnia pulex living near smelters in the Sudbury region of Ontario that have faced severe metal stress for over 100 years. These studies are possible because (1) well annotated genome and transcriptome sequences are available for this species whose ecology is well understood and (2) sophisticated tools for high-throughput biology allow for functional interrogation of the sequence information. We identified genotypes living in lakes from this region that have genetically adapted to cadmium stress. These isolates show no differences in their life history parameters when comparing control and cadmium exposed Daphnia. By contrast, cadmium exposures significantly decrease reproductive success in non-adapted Daphnia. Our studies also indicate that no fitness costs are imparted on these adapted Daphnia in the absence of metals, which differs from our observations of animals physiologically acclimated to cadmium through multiple generations. Adaptation produced different patterns of gene expression in metal exposed Daphnia. To explore the genomic basis for gene-expression differences, gene copy number was mapped across the entire transcriptome of metal-adapted and non-adapted Daphnia and these were compared to the sequenced reference genome. A large amount of copy number variation (CNV) was observed between individuals, including interesting contributions of CNV to the adapted phenotytpe. For example, cadmium adapted Daphnia contain additional copies of several genes that result in the increased dosage of transcripts for genes that contribute significantly to the adapted phenotype. These studies which begin to detail the genomic basis for adaptation in natural populations both contribute to and benefit from the Daphnia Genomics Consortium.

## ET13 - Moving towards a systems biology approach to predictive ecotoxicology

**ET13-1**

**Mapping drug physicocChemical features to pathway activity reveals molecular networks linked to toxicity outcome**

P Antczak[1], C Vulpe[2], F Falciani[1]
[1]University of Birmingham, BIRMINGHAM, United Kingdom
[2]University of California Berkley, BERKLEY, United States of America

The identification of predictive biomarkers is at the core of modern toxicology. So far a number of approaches have been proposed. These rely on statistical inference of toxicity response from either compound features (i.e. QSAR), in vitro cell based assays or molecular profiling of target tissues (i.e. expression profiling). We have previously published an analysis strategy that integrates pathway activity indices derived from gene expression data with physico-chemical features (PCFs) derived using QSAR and its application to a rat model of renal tubular degeneration. Our results indicated the importance of signalling pathways in response to chemical exposure. To identify pathways within a species important in eco-toxicology we have applied this method to a dataset derived from *Daphnia Magna*. Similarly to our previous results in *Rattus Norvegius*, *Daphnia Magna* also seems to respond to chemical exposure by modulating signalling pathways, suggesting an existence of a general toxicity mechanism, shared between the two different species, in synergy with more individually specific single-target based mode of actions.

**ET13-2**

**A network biology approach to ecotoxicology reveals novel pathways linked to environmental chemical exposure**

F Falciani, TD Williams
University of Birmingham, BIRMINGHAM, United Kingdom

Omics techniques have previously been applied to study marine pollution, but hitherto linkage to health outcomes and prediction of the composition and molecular mechanisms of action of complex pollutant mixtures has been lacking. To address these challenges, we have used a network inference approach to integrate multi-level datasets representing European flounder fish sampled from seven locations in the Irish Sea and North Sea.
Fish sampled from seven different sites in the North Sea were characterised at molecular and physiological levels using an unprecedented set of assays including histopathology, standard biomarkers, microsatellite markers and hepatic transcriptomics and metabolomics. Encouraged by the observation that the overall molecular state of the fish liver is predictive of the profile of contaminants at different sites and with the purpose of identifying molecular pathways linked to adaptation and adverse outcome, we set to develop an interpretative framework based on inference of a molecular network integrating the multi-level datasets.
This approach allowed the identification of two sub-networks whose activity was predictive of environmental exposure and linked to morphometric indexes such as liver weight. At the functional level these were representing both known and candidate novel adverse outcome pathways. Novel pathways were representative of several aspects of human liver pathophysiology such as liver hyperplasia, fibrosis, and hepatocellular carcinoma

**Modeling spatio-temporal dynamics within living cells**

J Mai[1], S Trump[1], R Ali[2], T Hanke[2], I Lehmann[1], S Attinger[1]
[1]UFZ - Helmholtz Centre for Environmental Research, LEIPZIG, Germany
[2]University of Technology, DRESDEN, Germany

Polycyclic aromatic hydrocarbons (PAHs), such as benzo[a]pyrene (BaP) represent an important class of environmental contaminants. PAHs are ubiquitous contaminants derived from tobacco smoke, automobile exhaust or incomplete combustion of organic matter in general. They exert a wide range of toxic effects including carcinogenic, immunosuppressive or pro-inflammatory responses. PAHs are known ligands of the aryl hydrocarbon receptor (AhR) signalling pathway. AhR is a ligand activated transcription factor important for detoxification of environmental agents, toxicology, the induction of inflammatory signals or the oxidative stress response.
Some central aspects of the AhR signalling pathway are understood: contaminants enter the cell, distribute in the cytosol and different cellular organelles and interact with the cytoplasmic AhR. Binding to the AhR triggers translocation of the receptor/ligand complex to the nucleus, the association with the AhR nuclear translocator and the interaction with xenobiotic responsive elements (XREs) at the DNA. This usually leads to enhanced expression of a number of genes, which are presumed to play a major role in deleterious effects of PAHs. In spite of this general knowledge of AhR-mediated signalling, little is known about the dynamic behaviour of AhR upon activation.
We observe the behavior of the cytoplasmic AhR as well as the AhR-complex inside the nucleus in living cells. We applied the Fluorescence Recovery After Photobleaching (FRAP) method which is a well known and widely used experiment to investigate parameters of motion and interaction. Within this work we present a general method to analyse FRAP data without using preassumptions. We applied the method to artificial datasets as well as real measurements on AhR. The analysis of the AhR measurements e.g. lead to predictions on concentration- and time-dependent binding of AhR to the XREs and might help to understand the quantitative relationship betweeen DNA bound AhR and the transcriptional response. Deduced parameters were used to set up a 3D simulation of AhR distribution upon activation based on realistic cell geometries. We introduce a general approach to determine parameters of dynamic processes inside the cell. This approach is applicable to various cellular systems expressing an fluorescent molecule of interest. The parameters deduced can be used for various applications to gain knowledge on the behaviour of cellular systems in different microenvironments.

**ET13-4**

**Predicting the reproductive fitness of Daphnia magna from metabolic signatures**

MR Viant, NS Taylor, A Gavin
University of Birmingham, BIRMINGHAM, United Kingdom

Molecular biomarkers have considerable potential as diagnostic tools in environmental toxicology and ecological risk assessment. One of the greatest challenges in environmental biomarker research is discovering molecular markers that are truly predictive of whole animal fitness and hence have ecological value, such as growth, energetic status and reproductive output. In this presentation we will describe a series of toxicity studies of Daphnia magna (the water flea). Specifically we have utilised mass spectrometry based metabolomics to measure the metabolic responses of individual daphnids to cadmium, propranolol and dinitrophenol, and in addition have measured their reproductive fitness (in terms of the number of neonates produced over a 21-day period). Multivariate regression analysis was then used to build mathematical models that can predict the whole animal reproductive fitness from the molecular signatures. In addition, multivariate classification methods were used to find metabolites that could predict the metabolic toxicity of these chemicals. Taken together, these findings highlight the genuine possibility that metabolomics can discover biomarkers that provide information on both molecular mode-of-toxicity as well as more ecologically relevant consequences for the whole organism.

**ET13-5**

**Marine diatom Thalassiosira pseudonana towards a system biology for the water quality assessment**

RCN Carvalho Negrão[1], SKB Bopp[2], AB Burchardt[1], FS Sena[1], TL Lettieri[1]
[1]EU JRC/Institute for Environment and Sustainability, ISPRA, Italy
[2]EFSA-European Food Safety Authority, PARMA, Italy

Diatoms are eukaryotic algae, living in oceans and freshwaters. They play a key role in the global carbon cycle, contributing to about 25% to the global primary production .
Genomics and proteomics tools have been used in the diatom T. pseudonana to study the effects of exposure to common aquatic pollutants. The purpose of such studies is to provide i) system biology approach to identify the key pathways linked to the exposure compounds, ii) selection of molecular biomarkers of exposure as early identification of water quality endangerment, iii) a more comprehensive substitute to mere water chemical analysis. We designed and customized a DNA Microarray to investigate the gene expression profile in T. pseudonana and used a quantitative proteomics approach based on isobaric tag labeling to identify and quantify the proteins which are regulated by chemical pollutant exposure. Benzo(a)pyrene, a polycyclic aromatic hydrocarbon (PAH), is one of well-known pollutants widely distributed in aquatic environments and it has been selected for pilot studies using a system biology approach. The diatoms were exposed to Benzo[a]pyrene (BaP) at a concentration which inhibits the growth by 30% . RNA and proteins were extracted to perform either the DNA Microarray analysis or quantitative proteomics. We identified more than 500 genes which were mainly invloved in processes e.g. oxidative stress, transcritpion regulation, lipid transport and metabolism and biosilification. At the protein level, although only 16% of the quantified proteins showed a regulation, five were regulated as well at gene expression level. One of these proteins is the silicon transporter 1 (ST1), an enzyme that is responsible for the uptake of silica, which is down regulated at both gene and protein levels. Furthermore, we showed that the BaP exposed cells reduced the uptake of silica from the media .
Our data shows that one of the processess clearly affected by BaP is the biosilicification process and we could link the gene-protein levels with the physiological state of diatom cells upon exposure to the pollutant. The use of a systems biology approch in diatoms will help to elucidate pathway/metabolic processes involved in the mode of action of pollutants and identitiy molecu-

lar biomarkers of exposure. This information can be used for the assessment of water quality in a more comprehensive way than other established protocols currently in use.

**ET13-6**

**Distinguishing regulatory and toxic transcriptional signatures of xenobiotic compounds**

S Trump[1], JJ Michaelson[2], S Rudzok[1], C Gräbsch[1], DJ Madureira[3], F Dautel[1], J Mai[1], S Attinger[1], K Schirmer[3], M von Bergen[1], I Lehmann[1], A Beyer[2]

[2]Biotechnology Center, TU Dresden, DRESDEN, Germany
[3]EAWAG Aquatic Research, ZURICH, Switzerland

Elucidating the transcriptional response of cells to chemical exposure is of primary importance for a reliable risk assessment of xenobiotic compounds like environmental pollutants. However, often such compounds trigger a complex cellular response. Dissecting these responses and identifying the transcriptional profiles associated with each individual (sub-) effect is essential for explaining side effects and predicting toxic responses of environmental contaminants.

One of the most studied transcription factors involved in the response to environmental pollutants or xenobiotic compounds in general is the aryl hydrocarbon receptor (Ahr). The Ahr has been studied for decades mainly because of its critical role in xenobiotic-toxicity and carcinogenesis. These well described toxic effects of Ahr stimulation are mainly due to the self induced activation of Phase I/II metabolizing enzymes, creating metabolites mostly responsible for the ultimately toxic response.

Using transcriptome time series of murine hepatoma cells exposed to the environmental contaminant benzo(a)pyrene (B[a]P), we investigate the hypothesis whether time resolved transcriptional signatures of genes that are direct Ahr targets differ from the profiles observed for genes responding to the toxic metabolite of B[a]P benzo(a)pyrene diol epoxide (BPDE).

We demonstrate that machine learning can be used for identifying these characteristic signatures and for subsequently classifying genes as to whether they are direct Ahr-dependent targets or indirectly affected (BPDE-dependent) genes. This is accomplished by training a Random Forest (RF) classifier to learn the difference between genes responding to B[a]P exposure and secondary effects caused by BPDE. The trained classifier is then applied to all genes found to be significantly differentially expressed in our time series as a result of B[a]P exposure, and their roles as direct targets or secondary effects are predicted. In addition, the patterns learned by the classifier are used as a basis for performing weighted clustering.

Introducing a new clustering approach we were able to reliably separate direct Ahr targets, among them twelve transcription factors, from genes activated due to secondary effects. Distinguishing the transcriptional profiles associated with the primary target effect from those acting in parallel is essential for understanding possible toxic side effects of such chemicals.

## ET14 - Natural toxins in ecotoxicology

**ET14-1**

**Analysis of microcystin algal toxins in Lake Maggiore water (N-Italy) by SPE-UPLC-MS-MS**

RG Loos[1], V Kisand[2], BM Gawlik[1]
[1]JRC IES, ISPRA, Italy
[2]Institute of Technology; University of Tartu, TARTU, Estonia

Algal blooms can generally occur in nutrient rich calm fresh waters and low salinity marine areas. Usually these blooms form in mid to late summer, and tend to float near the water surface.

A special type of cyanobacteria (blue-green algae) can produce toxins, called microcystins, which are cyclic peptides. The most important (most often analysed and found) species is microcystin LR.

People (and other mammals) can get sick from microcystin toxins if they have direct contact with a toxic algal bloom by swallowing water, or by having skin contact. Microcystin poisoning can cause breathing problems, stomach upset, nausea, vomiting, diarrhea, headache, fever, allergic skin reactions (a rash or skin blisters), and even liver damage.

Lake water samples (400 ml) were extracted by solid-phase extraction (SPE) at neutral pH using Oasis HLB 200 mg cartridges; elution: 6 ml methanol. Analyses were performed by ultra performance liquid chromatography (UPLC) triple quadrupole mass spectrometry (tq-MS) using a 50 x 2.1 mm (particles 1.7 um) column; eluents: water and acetonitrile (both 0.1% acetic acid); injection volumne 5 ul; Waters Aquity UPLC coupled to an AB Sciex 5500 Qtrap MS-MS; microcystins can be detected in the positive or negative ionization modes.

Very high SPE recoveries of around 97 % (n=4) could be achieved (at neutral pH). UPLC-MS-MS sensitivity is in the low ug/L concentration range, and overall method detection limits (including SPE enrichment) are lying in the low ng/L concentration range.

Some water samples from Lake Maggiore (and other smaller lakes) taken at the end of August and beginning of September 2010 were analysed. Microcystin LR was detected in all samples at low ng/L concentration levels, with a maximum found at ~ 350 ng/L. In this sample, also microcystin RR and LF were detected. Contamination depends strongly on weather (wind) conditions and currents. No microcystin LR was found in tap water.

The formation of microcystins is favoured by high summer temperatures, nutrient-rich (eutrophication) and calm water conditions. In the future, contamination might increase due to changing climatic conditions. More spatially and temporally spread monitoring and research on other algal toxin is necessary.

**ET14-2**

**Trophic transfer of microcystins from Lymnaea stagnalis (Gastropoda Pulmonata) to Gasterosteus aculeatus (Teleostei Gasterosteidae) and impact on the fish**

E Lance[1], A Petit[1], W Sanchez[2], C Gérard[1], M Bormans[1], DW Dietrich[3]

[2]Institut National de l'Environnement Industriel et des Risques, VERNEUIL EN HALATTE, France
[3]Faculty of Biology, KONSTANZ, Germany

Due to eutrophication of freshwaters, the frequency of cyanobacteria proliferations is increasing worldwide. From 40 to 75% of cyanobacterial blooms produce hepatotoxins [e.g. microcystins (MCs)], endotoxins released in water during the cell lysis and which constitute a real threat for target organisms as gastropods (intoxication by absorption of toxic cyanobacteria or dissolved toxins). MCs mainly accumulate in the liver (or digestive gland) of metazoans where they interact reversibly (free MCs) or irreversibly (covalently bound MCs) with phosphatase proteins, leading to tissues destruction. We previously demonstrated that the gastropod Lymnaea stagnalis ingested MC-producing cyanobacteria and accumulated free and bound MCs. As bound MCs persisted after a 3-week depuration period and represented up to 90% of total MCs, L. stagnalis is potentially a MC-vector through the food web. The aim of this study is to evaluate if free and bound MCs accumulated in L. stagnalis tissues are transferred to the three-spined stickleback, Gasterosteus aculeatus, and what are the consequences on this latter in terms of: 1) MC accumulation and elimination, 2) histopathology of the liver, 3) oxidative stress response, and 4) behavioural changes. Fish accumulated MCs (up to 3.9 ± 0.1 µg g-1 DW) in the liver, kidneys, muscles, and gills, showed an increased activity of glutathione peroxidase in the liver associated with a moderate pathology, and a decrease of the locomotory activity. During depuration, from 92 to 100% of free MCs were eliminated in all organs excepted in muscles (from 6 to 58%), suggesting that MC accumulation in G. aculeatus after consumption of intoxicated gastropods may induce a second transfer in aquatic and terrestrial food web, and possibly a human contamination.

**ET14-3**

**Is the invasive Dreissena polymorpha better adapted to cyanotoxin exposure than the native Unio tumidus?**

V Burmester[1], C Wiegand[2]
[1]Leibniz-Institute of Freshwater Ecology and Inland Fisheries, BERLIN, Germany
[2]University of Southern Denmark, ODENSE, Denmark

Freshwater mussels as *Dreissena polymorpha* and *Unio tumidus* with high filtration activities may accumulate cyanobacteria and their toxins during cyanobacterial blooms and lysis. Physiological adaptations to cyanotoxins enable organisms to live in cyanobacterial contaminated waterbodies. In contrast to *U. tumidus*, the invasive *D. polymorpha* seems to be a moderate sensitive species able to develop sustainable population in contaminated waterbodies. The population of Unionidae is endangered by water pollution, shoreline construction and competition with *D. polymorpha*. Competition is for food, as the habitats are different: the unionids need soft sediment, whereas *D. polymorpha* attaches to any kind of hard substrate, including shells of unionids.

This study compares the two species with regard to their detoxification capacity for microcystin, the most common cyanotoxin in freshwater. A further aim was to correlate the detoxification attempts to the physiological costs for the organisms. For this, the activities of biotransformation (glutathione S-transferase), antioxidant enzymes (superoxide dismutase and catalase) and energy reservoirs (glycogen-, lipid- and glutathion content) were compared in the invasive *D. polymorpha* and the native *U. tumidus* in response to cyanotoxin exposure (10 and 50 µgL-1 microcystin-LR) for 24 h and 7 d.

Enzyme activities of *D. polymorpha* were measured in whole mussel tissue, digestive gland and gills. Energy reserves were measured in whole mussel tissue. Enzyme activities and energy reserves of *U. tumidus* were measured in digestive gland, gills, mantle and foot. The sGST activities were increased for the whole exposure period in *D. polymorpha* but didn`t changed in *U. tumidus*. The catalase activity was not affected during the whole period in both species. The glycogen content decreased after 24 h in both species indicating the energy requirements due to the stress caused by the MC-LR exposure. We conclude that *D. polymorpha* is capable of detoxification of MC-LR but at expense of energy. The results suggest that *U. tumidus* is less able to detoxify MC-LR via biotransformation enzyme GST. Nevertheless, there was an enhanced requirement for energy, as indicated by reduced glycogen contents in both mussel species. Compared to *U. tumidus* the invasive *D. polymorpha* seems to be better adapted to cyanotoxin exposure.

**ET14-4**

**The use of single ecosystemfunction for a sustainible removal of cyanobacterial toxins from water**

CS Romero-Olivera, S Pflugmacher
Berlin Institute of Technology, BERLIN, Germany

Cyanobacterial blooms are a worldwide problem due to the eutrophication of water bodies. Most the cyanobacteria known today are producing toxins, from which the microcystins are the most common detected. Over 70 congeners of microcystins have been isolated (Carmichael, 1997). Microcystins are known to be potent inhibitors of protein phosphatase 1 and 2A and also known to be tumor promotors. During senescence of cells the toxins are released into the water in high amounts. The microcystins itsself are very stable molecules and highly persistent in the water (DeFigueiredo et al 2004).

In many countries, namely the semi-aride and aride ones, freshwater lakes are used for aquaculture, spray irrigation of agricultural plants and also as a source for drinking water (Nimptsch et al. 2008). There are several studies on how to remove cyanobacteria respectively their toxins from the lake water. Some of these studies are using clay particles, or hey bale to get rid of the cyanobacteria. But in most cases the toxins itsself stay in the water body.

Aim of our research is to identify and use single ecosystem functions, which can help in remidiation of cyanotoxins from lake water in a sustainible way. The single ecosystem function are e.g. the biology of aquatic macrophytes and their ability to take up toxic substances.

**ET14-5**

**Occurence of biotoxins in mussels from different coastal locations and risk management**

PD Hansen[1], B Luckas[2], U Unruh[1]
[1]TU Berlin, BERLIN, Germany
[2]Friedrich Schiller University, JENA, Germany

The Biotoxins (Red Tide) is an ecological and economic problem concerning aquaculture and tourisim in the coastal areas world wide. The neurotoxic, immunotoxic and genotoxic effects of domoic acid produced by the diatom *Pseudonitzschia multiseries* and saxitoxins (STX) paralytic shellfisch poisoning -PSP) produced by *Alexandrum catenella* and *Alexandrum ostenfeldii*. In addition the flagellate *Dinophysis acuta* produces the Diarrhetic Shellfish Poisoning (DSP). The need for increasing quality control at different critical steps of the food production chain has to be addressed by developing a set of rapid biomarker and sensor systems.

## ET16 - Soil ecotoxicology and quality assessment

**ET16-1**

**Effects of slurry from sulfadiazine (SDZ) treated pigs on the structural diversity of microorganisms in rhizosphere soil**

R Reichel[1], I Rosendahl[2], W Amelung[2], S Thiele-Bruhn[3]
[1]University of Trier, TRIER, Germany
[2]INRES-Soil Science and Soil Ecology, University of Bonn, BONN, Germany
[3]Soil Science, Faculty of Geography/Geosciences, University of Trier, TRIER, Germany

Efficient agricultural production frequently includes the use of veterinary antibiotics, consequently, manures from antibiotic-treated animals are disposed on arable soils. Antibiotics, co-applied with nutrient sources like manure, are increasingly reported to change soil microbial community structures in un-rooted bulk soil. However, the antibiotic effects in the rhizosphere soil compartment are not well understood. Therefore, a 60-d mesocosm study with maize plants in Luvisol, treated with sulfadiazine (SDZ) by a single manure application was performed. We hypothesized, that compared to bulk soil, antibiotic effects are dissimilar in different soil microcompartments and even more pronounced in soil affected by the presence of maize roots. In contrast, while antibiotic effects on community changes were temporally significant in bulk soils, effects in rhizosphere could not be revealed, using endpoints such as total community DGGE or PLFA patterns. This finding was related to stronger dissipation, and thus lower bioaccessibility of SDZ in the rhizosphere. However, antibiotic effects in rhizosphere soil were detected when investigated on specific pseudomonas community level. These results show that it is not sufficient to investigate homogenized soil material but the heterogeneity of soils must be considered in ecotoxicology testing, which leads to a diverse effectiveness of contaminants.

**ET16-2**

**Changes of metal availability over time in sludge-amended and metal-spiked soils. Does earthworm activity influence those changes?**

TMF Natal Da Luz[1], G Ojeda[1], M Costa[2], F Miranda[2], Z Lopes[2], J Pratas[3], RP Lanno[4], CAM van Gestel[5], JP Sousa[1]

[3]Dept. Earth Sciences - Universidade de Coimbra, COIMBRA, Portugal
[4]Dept of Evolution, Ecology, and Organismal Biology, Ohio State University, COLUMBUS, United States of America
[5]Dept of Animal Ecology, Faculty of Earth and Life Sciences, Vrije Universiteit, AMSTERDAM, The Netherlands

Total metal concentration is used to regulate sewage sludge application on soils. However, the real toxic risk posed by metals is determined by the fraction that is biologically available for the organisms, which is dependent on matrix of contamination (e.g. via sludge or metal solution) and various physical and biological processes (e.g. earthworm activity) which vary with time. Monitoring metal fate in soil over time using chemical extractions and measuring body residues in earthworms allows a clear understanding of changes in bioavailabilty and a better prediction of their effects. Comparative evaluations of changes in the availability over time in the presence and absence of earthworms of a certain pool of metals originating from sludge or from a metal spike in soil were performed. The objectives of this study were i) to evaluate changes in the availability of metals over time in metal-spiked and sludge-amended soils on short-term (under laboratory conditions) and long-term basis (under field conditions); ii) to assess the influence of the activity of a realistic density of earthworms on changes of total and extractable metal concentrations; and, iii) to measure metal uptake by earthworms from different test matrices. With these purposes, a laboratory and a field experiment were conducted. Treatments consisted of dose gradients of a sludge mainly contaminated with chromium (Cr), copper (Cu), nickel (Ni), and zinc (Zn; sludge-amended soils), and similar concentration gradients of the same pool of metals applied directly to the soil (metal-spiked soils). Half of the treatments were inoculated with a density of 500 Dendrobaena veneta per m2. Total and 0.01 M CaCl2 extractable metal concentrations were measured in soil samples and internal metal concentrations in the earthworms. Results demonstrated that the sludge matrix generally contributed to increased adsorption and reduced mobility of metals in soil. Environmental factors (e.g. plant roots and generality of edaphic fauna activity) induced decreases in metal extractability and the activity of a realistic density of D. veneta did not affect metal availability in test treatments over at least 12 months. Ni bioaccumulation was influenced by the test matrix and D. veneta was able to regulate its Zn internal concentration.

**ET16-3**

**Evaluation of soil compaction effects on soil organisms and soil biological processes**

BM Wilke[1], A Beylich[2], H Oberholzer[3], St Schrader[4], H Höper[5]
[1]TU Berlin, BERLIN, Germany
[2]IFAB Institute fuer Angewandte Bodenbiologie, HAMBURG, Germany
[3]ART Research Station Reckenholz, ZÜRICH, Switzerland
[4]J.Heinrich v. Thünen Insitut, Institut für Biodiversität, BRAUNSCHWEIG, Germany
[5]Landesamt für Bergbau, Energie und Geologie, HANNOVER, Germany

Investigations on soil compaction focused mainly on effects on soil physical parameters and on plant growth. Nevertheless, a substantial number of papers deal with effects of soil compaction on soil organisms (soil fauna, soil microorganisms) and biologically driven processes in soils (e.g., macropore formation, respiration rates, N-mineralisation). In view of soil protection and the protection of soil functions, there is an essential need to identify soil compaction threshold values with respect to soil biota and soil biological processes. No such values are currently available. Thus the aim of our study was to evaluate literature on the effects of soil compaction on soil organisms and soil biological processes (e.g., respiration, nitrification); to identify relevant parameters which are helpful for assessing soil compaction from the soil biological point of view; and to find out whether threshold values of soil structure parameters proposed by soil physicists correspond to harmful impacts on soil organisms and biological processes in soils. Our literature review showed that due to the high variability of experimental situations and conditions in the evaluated papers, especially in papers describing field investigations, no general effect of soil compaction was found. Negative and positive effects occurred with slight compaction as well as with strong compaction. A verification of the thresholds published to date for soil compaction was not possible based on the data evaluated. However, the fact that above an effective bulk density of 1.7 g cm-3, only negative effects on microbial biomass and C-mineralisation were found confirms this value, proposed by soil physicists, also from the soil biological point of view.

**ET16-4**

**Biomarkers and energetic reserves in isopods: the effects of long-term exposure to dimethoate**

GC Ferreira, MJG Santos, SMV Soares, S Loureiro
CESAM & Dep. Biology, University of Aveiro, AVEIRO, Portugal

The aim of this work was to evaluate the biomarkers activity and energy reserves content in a long-term exposure to the pesticide dimethoate, followed by a recovery period.

Organisms were exposed to soil contaminated with dimethoate in concentrations of 0.4 mg/kg soil (real case scenario) and 10 mg/kg soil (below EC50 value), plus a control. Replicates of 5 animals were collected at time 0, 24h, 48h, 96h, 7-days, 14-days, 21-days and 28-days. After this period animals were changed to boxes with clean soil and replicates were collected after 7-days and 14-days of recovery.

Biomarkers acetylcholinesterase (AChE), lactate dehydrogenase, lipid peroxidation, glutathione S-transferases, glutathione peroxidation, catalase, glutathione reduced and glutathione oxidized along with energy content (lipids, sugars and proteins), energy consumption and cellular energy allocation were measured.

As expected a strong inhibition was observed in acetylcholinesterase as the main target of the pesticide. Although a previous study had stated that organisms have low survival chances under neurotoxic regimes i.e. where AChE inhibition is higher than 80%, we observed a 7 day survival period with AChE inhibitions higher than 90%. Other biomarkers as lipid peroxidation presented significant differences when compared with the control at periods where high mortality rates were counted.

Energy reserves content, energy consumption and cellular energy allocation rate significantly fluctuated along time exposure and recovery.

The results show not only correlations between several biomarkers, the energy reserves and mortality, but also with other detoxification processes not related with neurotoxicity.

The present work showed that several sub-individual biomarker activity can be used as early warnings for Environmental Risk Assessment, and that sub-individual effects can be linked with ecologically relevant parameters (e.g. mortality and energy reserves content)

**ET16-5**

**Development of a new plant-based biotest to assess trace element phytoavailability in contaminated soils - Selection of target-plant species for standardisation**

MN Bravin[1], L Lemal[2], P Hinsinger[2], E Doelsch[1]
[1]CIRAD, SAINT DENIS CEDEX 9, LA RÉUNION, France
[2]INRA, MONTPELLIER, France

Concerning the threat of soil contamination, the assessment of trace element phytoavailability at an operational level still requires the identification, the development and the standardisation of a set of biological methods (i.e. biotest). The present abstract introduces the first step in the development of a new plant-based biotest, the RHIZOtest, focused on the selection of the target-plant species suggested for the standardisation of the RHIZOtest.

The RHIZOtest is notably based on a complete physical separation between plant and soil compartments enabling an easy, fast and clean recovery of the roots. The RHIZOtest was deployed for ten plant species commonly used in agriculture and on three soils exhibiting a broad range of pH and a high concentration in several trace elements. The measurement of trace element phytoavailability was finally achieved as the mean flux of trace element to the plants during the exposure of the plants to the soil.

Seven out of ten plant species exhibited homogenous growth of roots and shoots and consequently can be used adequately in the RHIZOtest experimental procedure. As expected, plant uptake flux of trace elements varied significantly and many-fold among the ten plant species tested. However, trace element phytoavailability also broadly varied among trace elements and soils. Finally, a procedure of ordination and scoring enabled us to select three plant species that maximised trace element phytoavailability according to a precautionary-like principle. This three plant species will be suggested for further standardisation of the RHIZOtest.

This study supports the requirement of biological methods that enable to encompass the biological diversity in the assessment of trace element phytovailability whereas chemical methods are not able to take it into account. Such kind of validation procedure for a biotest is the unique opportunity for achieving operational methods based on a hard scientific background that could be standardised for the assessment of trace element phytoavailability.

**ET16-6**

**Use of the Comet and micronucleus assays in the detection of genotoxic effects in Eisenia andrei coelomocytes after exposure of the earthworms to dioxin and B[a]P-spiked soils**

SS Sforzini[1], M Boeri[1], I Saggese[1], L Oliveri[1], C Bolognesi[2], A Viarengo[1]
[1]University of Piemonte Orientale, ALESSANDRIA, Italy
[2]Environmental Carcinogenesis Unit IST, GENOVA, Italy

Many organic pollutants bring about not only general toxic effects, but are also genotoxicants, meaning they can alter both the structure and the integrity of DNA, either directly or indirectly. The evaluation of genotoxicity biomarkers is of particular importance, considering the relevance of these data in terms of possible carcinogenic risk not only for edafic communities but also for humans. In this study, earthworms of the species Eisenia andrei were exposed for 10 and 28 days to different sublethal concentrations of Benzo[a]Pyrene (B[a]P) (0.1, 10, 50 mg/kg) and 2,3,7,8 tetrachlorodibenzodioxin (TCDD) (1x10-4, 1x10-5, 2x10-3 mg/kg) mixed into a standard artificial soil. The selected B[a]P and TCDD concentrations were, beginning with the lower ones, the Italian law limit for residential areas, for industrial areas, and 5 and 20 times higher respectively. The level of DNA damage, using the Comet assay, was assessed in earthworm coelomocytes. Taking into account the relevance in assessing the chromosomal damage to provide evidence of fixed lesions to the genetic material, in the same cells, the induction of cytoplasmic micronuclei (MNi) was also studied by cytochemical staining of DNA by the fluorescent dye DAPI. MNi were scored according to standardized criteria. In addition, the presence of the contaminants in the earthworms was investigated by chemical and immunohistochemical analyses. Cryostat tissue sections were reacted with specific anti-B[a]P and -TCDD antibodies. The results obtained showed that, although no effect on mortality was found, the Comet and MN assays were able to reveal genotoxic effects. Also, and in particular, the two lower concentrations of the chemicals utilised, induced, just 10 days after the exposure, both DNA and chromosomal damage in earthworm cells. In the treated animals, the immunohistochemical staining revealed the distribution of the pollutants both in the coelomocytes and in the different tissues. In this work we demonstrated that the Comet assay and MN test in E. andrei coelomocytes should be considered sensitive biomarkers of genotoxicity within an environmentally realistic range. The use of immunohistochemistry for detecting environmental contaminants like B[a]P and TCDD is valuable in demonstrating a potential link between the presence of the chemicals in the organisms and the occurrence of toxic/genotoxic effects and in addressing chemical analyses in greater depth.

## HM01 - Characterisation and remediation of contaminated soils and sediments

## HM01-1

**Phytoremediation: simultaneous calibration of contaminant sorption and plant uptake**

F Lugli, MTh van Genuchten, CF Mahler
Universidade Federal de Rio de Janeiro, RIO DE JANEIRO - RJ, Brazil

Phytoremediation is an emerging technique that stands out for its simplicity and low cost. Compared to traditional techniques, phytoremediation leads to slower and generally more uncertain results because of the many complexities affecting the soil-plant-atmosphere environment. This study focuses on numerical simulations of phytoremediation data of metal polluted soils using the Hydrus-1D software package, a potentially useful tool for evaluating the efficacy of alternative remediation techniques. Data used for the analysis were derived from experimental phytoremediation study using pots planted with Vetiver grass, and with the soil contaminated with $Ni^{2+}$, $Pb^{2+}$, $Cd^{2+}$ and $Zn^{2+}$. Available data were basic soil physico-chemical properties, meteorological information, the applied irrigation scheme, and metal concentrations in the plants. Variably-saturated flow was described using the standard Richards' equation, and solute transport using the advection-dispersion equation. Sink terms in the governing flow and transport equations accounted for root water and solute uptake, respectively. Plant growth and compartmentalization of the contaminants within the vegetation, were not considered. Sorption of metals by the solid phase was described using linear isotherms. Numerical simulations showed hydraulic conditions consistent with the experimental data. Three calibrations were considered (passive metal uptake, passive metal uptake with sorption adjustments, and active metal uptake). Simulated metal accumulations in the dried mass of the plants were compared to phytoextracted data. Passive uptake simulations showed good agreement with the experimental data for $Pb^{2+}$ and $Zn^{2+}$ ($R^2$ values were 0.7435 and 0.8526, respectively) but they significantly overestimated data for $Ni^{2+}$ and $Cd^{2+}$ (up to five times). For these metals it was necessary to use an active solute uptake model (yielding $R^2$ values 0.9884 and 0.9911 for $Cd^{2+}$ and $Ni^{2+}$, respectively). Improved simulations of $Pb^{2+}$ and $Zn^{2+}$ uptake were further possible by adjusting the linear distribution coefficient for sorption. This study shows that it was possible to achieve good calibration of the metal phytoextraction process by Vetiver grass as observed by a series of controlled pot experiments. The adopted numerical approach for analyzing phytoremediation appears very promising for application to more dynamic field conditions.

## HM01-2

**Evaluation of arsenic phytoextraction efficiency of Pteris vittata under field conditions**

C Bettiol[1], F Minello[1], E Bona[2], G Berta[2], P Criscione[3], A Bonfà[3], E Argese[1]
[1]Ca' Foscari University, VENEZIA, Italy
[2]Università del Piemonte Orientale, ALESSANDRIA, Italy
[3]STA s.r.l., VENEZIA, Italy

The Chinese brake fern *Pteris vittata* is a well known arsenic hyperaccumulator plant and possesses features that can make it an ideal species for phytoremediation of As contaminated sites: fast growth rate, high biomass production and a high efficiency of As translocation from roots to fronds. Extensive research has been carried out using this plant under laboratory and greenhouse conditions, while more limited information is available on the behaviour of P. vittata when plants are grown directly in the field.

This study summarizes and compares the results of field experiments conducted with this plant in contaminated sites located in northern Italy, characterized by different levels of contamination and soil characteristics. The research was aimed not only at estimating As extraction efficiency, but also at evaluating the most critical parameters for plant growth, since *P. vittata* is not a native species. Various experimental conditions have been tested, such as plant age, presence of other contaminants, influence of agronomic practices. In addition, the effect of mycorrhizal symbioses on plant growth and on arsenic phytoextraction efficiency was also investigated.

*P. vittata* showed in general a high phytoextraction efficiency, but plant growth and survival were strongly affected by adverse pedoclimatic conditions. Mycorrhization had a positive effect on plant growth; however, it was not possible to point out a clear influence of mycorrhization on As phytoextraction.

## HM01-3

**Assessing the impact of sediment contamination on benthic macroinvertebrates in freshwater tidal ecosystems**

HJ de Lange[1], ETHM Peeters[2], AJG Reeze[3], M de la Haye[4], J Postma[5]
[1]Alterra, Wageningen UR, WAGENINGEN, The Netherlands
[2]Wageningen University, WAGENINGEN, The Netherlands
[3]Arcadis, APELDOORN, The Netherlands
[4]Grontmij Aquasense, AMSTERDAM, The Netherlands
[5]Ecofide, WEESP, The Netherlands

The Rhine-Meuse delta is located in the south-west of the Netherlands, and contains the largest freshwater tidal ecosystem in the Netherlands. Historic pollution of the rivers Rhine and Meuse has resulted in the presence of different kind of contaminants (PAHs, PCBs, trace metals) in the delta sediments. The objective of this study is to present an approach and a system for evaluating sediment contamination using benthic macroinvertebrates. Data on habitat characteristics, sediment contamination and macroinvertebrate community structure were available for > 500 locations in the delta, in the period 1993 - 2006. The data were analyzed using various multivariate statistical analyses. This resulted in the construction of two metrics to be used within the Water Framework Directive in the Netherlands. The newly developed metrics correlated individually better than any of the existing metrics, combining both new metrics they performed much better than the combination of three existing metrics. The two metrics are now implemented in the WFD assessment of the Dutch R8 river type. A first validation of the metrics to new data showed that they performed quite well. Further testing of these metrics on other areas should show if the metrics should be adjusted using a traits-approach.

## HM01-4

**Sediment remediation with activated carbon: Modeling the trade-off between PAH toxicity reduction and negative activated carbon effects on macroinvertebrate populations**

D Kupryianchyk, MI Rakowska, JTC Grotenhuis, AA Koelmans
Wageningen UR, WAGENINGEN, The Netherlands

Activated carbon (AC) addition to contaminated sediments leads to reduction of bioavailable fractions of hydrophobic compounds (HOCs), and thus, toxicity of sediment-bound HOCs. However, it has been shown that AC itself may cause some negative effects on aquatic organisms, e.g. mortality, growth and ingestion rate inhibition. The aim of this study was to simulate the combine effect of polyaromatic hydrocarbons (PAHs) and AC amendment on biomass development on two benthic species, Gammarus pulex and Asellus aquaticus. Dose-response relations derived from a series of laboratory experiments were used to calibrate and evaluate the model. AC addition has no effect on biomass development of A. aquaticus but addition of AC>3% leads to inhibition of biomass development of G. pulex by 50%. In polluted sediments without AC, the effect of PAHs was severe and led to extinction of both species population within several days. Addition of AC drastically reduced mortality rates leading to growth of the populations. In summary, at higher concentrations, AC might have an effect on biomass development of some sensitive species like G. pulex. However, overall effects AC addition to PAH contaminated sites are predicted to be positive as long as AC is added at optimum concentration (3%).

## HM01-5

**Towards the phytoremediation of mining explorations - a NATO SfP project**

CR Marques[1], A Mistiri[2], C Rodrigues[3], C Santos[4], J Pinheiro[4], S Bouguerra[2], I Lopes[4], B Santos[4], G Pinto[4], A Haddioui[5], M Ksibi[2], F Gonçalves[4], N Gomes[4], S Mendo[4], J Römbke[6], P Sousa[3], R Pereira[4]
[1]University of Aveiro, AVEIRO, Portugal
[2]Laboratory Water, Energy and Environment LR3 (ENIS), SFAX, Tunisia
[3]IMAR-CIC, Department of Zoology, University of Coimbra, COIMBRA, Portugal
[4]CESAM & Department of Biology, University of Aveiro, AVEIRO, Portugal
[5]University of Sultan Moulay Slimane, Faculty of Science and Techniques, BENI-MELLAL, Morocco
[6]ECT, FLÖRSHEIM, Germany

In different NATO and Mediterranean Dialogue countries the mining exploration was or still is, an important economic activity. Along with it, is left a legacy of contamination problems represented by the exposure to metal and radionuclide compounds which become a risk to the aquatic, terrestrial and human health. This Science for Peace NATO project gathers Ecotoxicologists, Microbiologists, Molecular Biologists, Chemists and Plant Physiologists to develop and improve eco-friendly techniques for the remediation of contaminated sites in Tunisia, Morocco and Portugal. More specifically, it intends to implement and optimize the phytostabilisation of metals and radionuclides based on the knowledge attained from plant-bacteria interactions in each country area. The first attempts regarded the application of a risk assessment framework to establish priority areas for further intervention. Secondly, it was isolated metal resistant strains of endophytic and rhizosphere bacteria from native plant roots collected in contaminated sites. Those strains have been characterized through the use of molecular techniques. The next step is to inoculate the roots of small plantlets from selected species with bacteria endophytes and assess their ability to promote plant growth in contaminated soils, under green house and in situ experiments. For that, it is also needed the assessment of plant species that could grow under such contaminated sites, in order to be a successful target for using in the phytoremediation process. The present communication aims to perform an overview of the project goals as well as to explain the experimental steps done so far and the preliminary results obtained.

## HM01-6

**Characterizing contaminant residuals from environmental dredging using chemical and biological metrics**

M Mills[1], R Brenner[1], J Lazorchak[1], J Meier[1], S Cieniawski[2]
[1]US EPA Office of Research and Development, CINCINNATI, United States of America
[2]USEPA - GLNPO, CHICAGO, United States of America

Environmental dredging is a common remedial action for managing contaminated sediments. However, post dredge concentrations in surface sediment are difficult to predict prior to initiating dredging actions. In some cases, post surface concentrations have been higher than anticipated. This research focused on methods to characterize post dredge residuals and develop an approach to predict post dredging residual contaminant characteristics and concentrations.

In Northeast Ohio on Lake Erie, the Ashtabula River was contaminated by a number of industrial sources over years of runoff and discharges. In 2006-2007, 1.1 miles of the river was dredged under the authority and leveraged funding of the Great Lakes Legacy Act. The dredging operation carried out over two fields season resulted in 540,000 cyds of contaminated sediments being dredged, dewatered, and placed in a CERCLA landfill. The primary contaminant driver for the removal action was PCBs at concentrations up to 600pm but also included radionuclides, metals, and other organic contaminants

EPA's Office of Research and Development conducted an interdisciplinary research study in association with the dredging operations on the Ashtabula River. The research had two primary goals: 1) quantifying the extent and characteristics of the residuals that remained following dredging in a selected river reach, and 2) characterize the ecosystem exposure that occurred during and following dredging on the entire dredged area. ORD's National Risk Management Research Laboratory (NRMRL) and National Exposure Research Laboratory (NERL) collaborated to leverage resources and expertise toward these goals along with the Great Lake National Program Office. Results of the study are presented on the approaches evaluated to characterize the post dredge residuals. Several approaches were evaluated to quantify and characterize the residuals remaining in two distinct dredge areas, dredging to soft sediment and dredging to bedrock. Comparison will be made between the two areas dredged, as well an evaluation of the methods for the dredge residual characterization. Biological indicators of system wide recovery will also be presented in relation to the dredge residuals.

# HM02 - Impact and remediation of wastewater

## HM02A-1

**Xenobiotic removal efficiencies in wastewater treatment plants: residence time distribution as a guiding principle for sampling strategies**

M Majewsky[1], T Gallé[1], M Bayerle[1], R Goel[2], K Fischer[3], PA Vanrolleghem[4]
[1]CRP Henri Tudor, ESCH-SUR-ALZETTE, Luxembourg
[2]Hydromantis, Environmental Software Solutions, Inc., HAMILTON, Canada
[3]University of Trier, TRIER, Germany
[4]ModelEAU, Départment de Génie Civil, Université Laval, QUÉBEC, Canada

The effect of mixing regimes and residence time distribution (RTD) on pollutants in wastewater treatment plants (WWTP) is well understood in hydraulic engineering. Nevertheless, it is often neglected in sampling design and data analysis investigating xenobiotic removal efficiencies in WWTPs. Most investigations on the latter rely on 24 h composite samples and the mean hydraulic retention time (HRT) used as time offset to match influent and effluent loads. However, disregarding the mixing regime characteristics in evaluating xenobiotic removal performances may lead to biased estimations or even negative mass balances.

This study aims to develop an approach to estimate xenobiotic removal efficiencies from monitoring data taking the hydraulic residence time distribution (RTD) in WWTPs into account. For this purpose, a completely mixed tanks-in-series model was used to address hydraulic mixing regimes in a Luxembourg WWTP. Emission predictions of the WWTP were validated with

measured diurnal effluent data for the pharmaceuticals carbamazepine and diclofenac as well as the complexing agents NTA and DTPA.
Influent loads (of 24 h) were found to be released as effluent distributions that clearly expand over more than one day. A 24 h effluent sampling period with an optimal offset (18 h) between influent and effluent recovered only half (55.6 %) of the influent load in a dry weather scenario and consisted largely of fractions from previous and even fractions of the following day(s). Knowing the influent concentrations and flows of 3 (or 4) consecutive measurement days, their fraction released during the chosen measurement period can be determined allowing to estimate the overall removal performance.
The presented study demonstrates that hydrodynamics are crucial for elimination efficiencies of xenobiotics in municipal WWTPs. The HRT is of limited used only since it actually contains no information about mixing behavior. Commonly reported negative mass balances for xenobiotics might therefore also be a consequence of biased sampling schemes. The optimal sampling setup for full-scale mass balancing at the selected WWTP was determined to be a coverage of 3-4 consecutive days in the inlet and a single day sampling at the outlet. This constellation allowed to capture more than 83 % of the incoming water under realistic conditions. Due to the influent variability elimination rates of less than 5-10 % are probably impossible to track in full-scale investigations.

### HM02A-2

**Restricted elimination of the non-ionic surfactant TMDD in WWTPs**

A Guedez O., W Püttmann
Goethe University Frankfurt am Main, FRANKFURT AM MAIN, Germany

2,4,7,9-tetramethyl-5-decyne-4,7-diol (TMDD) is a non ionic surfactant that has been found in different rivers in Germany with concentration up to 4.25 µg/L. The compound is a high production volume chemical which is used in diverse applications such as colours, inks, adhesives and coatings but until now the sources of TMDD in the aquatic environmental are unknown. Wastewater treatment plants (WWTPs) were suggested to be the dominating sources for TMDD in rivers, but information neither about the TMDD concentrations nor about its elimination rates in WWTPs are available so far. Therefore, detailed sampling campaigns at 4 WWTPs in Germany were carried out. The results indicate that TMDD is introduced by the sewage with loads fluctuating between 10.1 g/d and 1142 g/d and it is discharged with effluents loads between <LOQ to 434 g/d into the rivers. Based on the load analysis, the elimination rates of TMDD in the studied WWTPs varied between 33% and 68%. The elimination rates in each treatment stage of one WWTP were also determined. The results indicate that TMDD in preferably degraded in the biological stages under aerobic conditions.

### HM02A-3

**Distinct transformation pathways of opium alkaloids in biological wastewater treatment**

A Wick[1], M Wagner[2], TA Ternes[1]
[1]Federal Institute of Hydrology, KOBLENZ, Germany
[2]Max Planck Institute for Polymer research (MPI-P), MAINZ, Germany

Recent studies confirmed that many organic micropollutants are transformed into unknown products during biological wastewater treatment. The emission of transformation products (TPs), which often exhibit only a slightly modified molecular structure and a higher polarity and persistency, has raised increasing concerns, since they are prone to contaminate drinking water resources and might exhibit a similar or even higher biological activity than the parent compounds. In this study, the aerobic transformation pathways of 4 natural opium alkaloids (codeine, morphine, dihydrocodeine and morphine) were elucidated using batch experiments with activated sludge. The complementary use of high-resolution mass spectrometry (HR-MS) and nuclear magnetic resonance (NMR) allowed for the identification of several up to now unknown transformation products (TPs). In total, chemical structures of 18 TPs of codeine, 17 TPs of morphine and 2 TPs of dihydrocodeine and hydrocodon were proposed. Elucidation of the transformation pathways in sterile (autoclaved) and non-sterile sludge suspensions revealed that the transformation of codeine and morphine is characterized by a variety of chemical (non-enzymatic) and biological (enzymatic) reactions. The development of a sensitive analytical method for quantification of several TPs of codeine in wastewater enabled to confirm that the results from the batch experiments can be transferred to full-scale WWTPs. The results of the study indicate that structurally closely related compounds such as the opium alkaloids might undergo distinct transformation pathways and highlight the importance to consider both chemical and biological reactions when predicting the transformation pathways of organic micropollutants in biological wastewater treatment.

### HM02A-4

**Are organic micropollutants more bioavailable in wastewater than common models predict?**

A Neale[1], A Antony[2], W Gernjak[1], G Leslie[2], BI Escher[1]
[1]The University of Queensland, BRISBANE, Australia
[2]The University of New South Wales, SYDNEY, Australia

The fate of micropollutants within the aquatic environment is influenced by their interaction with dissolved organic carbon (DOC). Only the freely dissolved concentration is bioavailable, while the fraction sorbed to DOC is not bioavailable. While most studies within the literature have focused on reference or natural DOC as a surrogate, very little is known regarding micropollutant interaction with wastewater derived DOC. An understanding of this interaction is important as there is increasing interest in recycling secondary treated effluent for non-potable and indirect potable applications, and the interaction with DOC may not only influence the bioavailability but also retention during membrane treatment processes. The aim of this study was to quantify dissolved organic carbon-water partition coefficients ($K_{DOC}$) for both reference and wastewater derived DOC with a range of micropollutants using a polydimethylsiloxane depletion method. The results indicated a significant difference in $K_{DOC}$ between reference and wastewater derived DOC for moderately hydrophobic micropollutants. For the most hydrophobic compounds, such as benzo(a)pyrene, sorption to wastewater derived DOC was over 1000 times lower than to reference DOC. The interaction of the estrogenic micropollutant nonylphenol with wastewater derived DOC from different stages of a wastewater treatment and advanced water treatment train was studied, but little difference in $K_{DOC}$ was observed. Analysis of the studied reference and wastewater derived DOC revealed that they have very different properties due to their different origins. The wastewater derived DOC was less aromatic and had a lower molecular weight due to microbial activity and this reduced the sorption capacity. In conclusion, a larger fraction of hydrophobic micropollutants are expected to be freely dissolved and thus bioavailable in wastewater than predicted using $K_{DOC}$ measured with reference DOC.

### HM02A-5

**A toxicity monitoring of industrial effluent: implications in the implementation of toxicity-based discharge limits in Korea**

J Jung[1], SB Kim[1], V Chounlamany[2]
[1]Korea University, SEOUL, South-Korea
[2]National University of Laos, VIENTIANE, Laos

In this study, the acute toxicity and feeding rate tests were applied to periodically monitor the toxic effects of effluents from a wastewater treatment plant (WWTP) using *Daphnia magna* (reference species) and *Moina macrocopa* (domestic species). Acute toxicity of industrial wastewater toward *D. magna* and *M. macrocopa* was largely reduced by primary biological treatment, thus subsequent effluents (PE, SE and FE) and stream waters (US and DS) showed either no acute toxicity or toxicity values less than 1 TU. In addition, the toxicity of final effluent (FE) varied over different sampling events, and *M. macrocopa* appeared to be more sensitive than *D. magna*. Among toxic metals, Cu concnetrations of FEs range from 0.002 - 0.067 mg $L^{-1}$, which are higher than $EC_{50}$ values (0.022 and 0.011 mg $L^{-1}$ for *D. magna* and *M. macrocopa*, respectively). However, acute toxicity more than 1 TU was not observed even in those samples. Considering concentrations of dissolved organic carbon (15.25 - 29.70 mg $L^{-1}$) in FE, reduction of free Cu concentration by complexation appeared to responsible for that. The feeding rates of *D. magna* and *M. macrocopa* were significantly reduced when compared to the control though acute toxicity was not observed. The feeding rate of *D. magna* was inhibited by the average of 50.8, 23.3 and 22.2% for the FEs, DSs and USs, respectively, while it was inhibited by the average of 58.6, 45.2 and 36.0%, respectively, when *M. macrocopa* was evaluated. The feeding inhibition of the DS over the overall sampling period was more significant than that of the US, suggesting that effluent from the PJ-WWTP likely had an impact on the S-stream. These findings suggest that a periodic monitoring of effluent with a domestic species (i.e. *M. macrocopa*) is desirable in the implementation of toxicity-based discharge limits in Korea. In addition, both the lethal and sublethal toxicity tests should be used to evaluate the impact of low levels of toxic chemicals in effluent.

### HM02A-6

**Whole effluent assessment of urban discharges**

HC Holten Lützhøft, S Qualmann, KO Kusk, PS Mikkelsen
Technical University of Denmark, KGS. LYNGBY, Denmark

The European Water Framework Directive and the Environmental Quality Standards Directive lay down a framework for maintaining or obtaining good ecological and chemical status of European surface and coastal water bodies by the year 2015. The aim of this work was through Whole Effluent Assessment (WEA) to identify problematic urban discharges, e.g. stormwater, municipal wastewater, combined sewer overflow (CSO), industrial wastewater. Samples from around Copenhagen were therefore tested in the Larval Development Ratio (LDR) test using the marine crustacean Acartia tonsa. The number of non-hatched eggs, nauplii and copepodites was determined in controls as well as in samples and the effect was calculated as the ratio between the number of copepodites and the sum of the numbers of nauplii and copepodites. Ratios below or above 1 significantly (t-test) differing from the control group are considered inhibited or stimulated, respectively, both indicating an effect of the stressor. Except for the stormwater, which did not show any effects at a concentration of 72%, all samples need to be diluted to more than 72%. Compared with the control group, the CSO from Belvedere needs to be diluted between 1,000 (P=0.001) and 10,000 (P=0.1736) times, the concentrate from the PP needs to be diluted around 1,000 (P=0.126) times and the outlet from the WWTP Damhusåen needs to be diluted at least 200 (P=0.001) times before the development of the organisms are comparable with the control group.

### HM02B-1

**Optimisation of Fenton reagents using central composite design for hybrid treatment of recalcitrant metal-working fluid wastewater**

S Jagadevan, P Dobson, IP Thompson
University of Oxford, OXFORD, United Kingdom

Disposal of operationally exhausted metal working fluids (MWF) biologically is an attractive option, since it is effective and has low energy demands. However, it is enormously challenging since they are chemically complex including the addition of toxic biocides which are added specifically to retard biodegradation whilst operational. In this study the feasibility of employing a sequential Fenton-biological oxidation for the treatment of recalcitrant components of MWF wastewater which were resistant to bacterial treatment was investigated. A statistical experimental design using Central Composite Design was employed to address Fenton reagent [H2O2, Fe2+] dose optimisation which ensured minimal concentrations of the reagents, thus making the treatment environmentally and economically viable. The results demonstrated that Fenton pre treatment of the recalcitrant MWF wastewater achieved an overall improvement in biodegradability (BOD5/COD increased from 0.160 to 0.538) with 92% and 85% reduction in COD and TOC respectively.

### HM02B-2

**Ozone and activated carbon treatment of sewage effluents: toxicity removal vs. toxicity increase**

D Stalter, A Magdeburg, J Oehlmann
University Frankfurt, FRANKFURT AM MAIN, Germany

Ozonation and activated carbon filtration provide effective barriers to a wide range of organic pollutants and can thus reduce the emission of hazardous contaminants via sewage treatment plant effluents. However, concerns arose about potential hazardous oxidation products occurring as a result of ozonation. Consequently, for a risk-benefit analysis, an extensive ecotoxicological evaluation of advanced treated wastewaters is essential. The presented work is part of a comprehensive study within the Neptune project (www.neptune-eu.org), covering in vivo tests with six different test organisms and a variety of in vitro bioassays.
For a comparative in vivo toxicity analysis, test organisms were exposed to raw wastewater from different sampling points onsite at two treatment plants in a flow through test system. Test organisms: Lemna minor, Chironomus riparius, Lumbriculus variegatus, Potamopyrgus antipodarum, Dreissena polymorpha and Oncorryhnchus mykiss. For the in vitro analysis, WW was solid phase extracted before toxicity testing. Toxicity endpoints using yeast based bioassays: (anti-) estrogenicity, (anti-) androgenicity, AhR agonistic (dioxin like) activity; tests on genotoxicity/mutagenicity: SOS/umu test, Ames fluctuation assay using different tester strains; test on non-specific toxicity: cytotoxicity assay using a rat pituitary cell line.
In vivo toxicity is increased after ozonation due to byproduct formation, whereas sand filtration appeared as an appropriate post treatment for byproduct removal/degradation. Solely activated carbon treatment revealed a significant reduction of in vivo non-specific toxicity compared to conventional treatment. Endocrine activity, genotoxicity and cytotoxicity of wastewater are effectively reduced with ozonation and activated carbon filtration, indicating the removal/degradation of causative contaminants. A consistent mutagenicity increase after ozonation confirms the for-

mation of toxic oxidation products in vitro and hence further research on byproduct formation and removal effectiveness of post treatments is desirable.

**HM02B-3**

**Evaluation of bioassays and wastewater quality: In vitro and in vivo bioassays for the performance review in the Project 'Strategy MicroPoll'**

C Kienle[1], R Kase[1], C Abegglen[2], J Margot[3], A Magnet[4], D Thonney[4], I Werner[1], M Schärer[5]
[1]Swiss Centre for Applied Ecotoxicology Eawag/EPFL, DÜBENDORF, Switzerland
[2]Eawag Aquatic Research, DÜBENDORF, Switzerland
[3]Ecole Polytechnique Fédérale de Lausanne (EPFL), LAUSANNE, Switzerland
[4]Wastewater treatment plant of Lausanne, LAUSANNE, Switzerland
[5]Federal Office for the Environment, BERN, Switzerland

The goal of the project "Strategy Micropoll" of the Swiss Federal Office for the Environment was to evaluate the efficiency of two advanced wastewater treatment technologies: (i) ozonation followed by sand filtration (SF), and (ii) powdered activated carbon addition followed by ultrafiltration (PAC-UF) in eliminating micropollutants from wastewater treatment effluent. Two large-scale pilot studies were conducted at the wastewater treatment plant (WWTP) Wüeri Regensdorf (Switzerland) and the WWTP Vidy Lausanne (Switzerland). The studies were done in close collaboration with experts from research, practice and with personnel and financial support of cantonal water protection agencies and the operators of the WWTPs.
Samples before and after each treatment step were analyzed for organic micropollutants and ecotoxicological effects, in order to gain insight into the efficiency of the different treatment steps. The focus lay on studying the effects of the advanced treatment technologies ozonation-SF and PAC-UF on the removal efficiency of polar, persistent and bioactive substances as well as possible by-products.
It was demonstrated that ozonation-SF and PAC-UF treatment are useful measures to reduce the effects of micropollutants in waterbodies. The overall elimination rate regarding specific effects was generally above 80%. Overall advanced treatment led to lowered risk quotients, i.e. the ratio between measured concentrations and environmental quality standards, as well as reduced toxicity in bioassays, and thus lowered risk of adverse effects. There was no evidence of toxic effects due to the formation of stable transformation products in the ozonation. However, a final filtration step with a biological activity (e.g. sand filter) after ozonation is recommended in order to reduce possible risks of transformation products released into water bodies.
In both pilot studies, the application of bioassays for the performance review of advanced wastewater treatment has proven to be relevant and useful. In general, *in vitro* bioassays were deemed most promising for the routine monitoring of the performance of advanced treatment in WWTPs, however only specific effects are assessed in those tests. Certain *in vivo* bioassays could also show the beneficial effect of ozonation and PAC-UF treatment such as the fish early life stage test (FELST) with *Oncorhynchus mykiss*. The quality of treated effluent was significantly improved, leading to improved surface water quality.

**HM02B-4**

**Using multiple lines of evidence to determine the major factors affecting ecosystem health in an urban stream**

V Pettigrove[1], C Claudette[1], S Long[1], L Golding[1], K Hassell[1], JH Myers[1], A Kumar[2]
[1]Centre for Aquatic Pollution Identification & Management, PARKVILLE, Australia
[2]CSIRO Land and Water, GLEN OSMOND, Australia

A study was conducted on an urban stream in Melbourne, Australia, to identify the major sources of pollution impacting aquatic ecosystem health. Sediment pollution was identified as a major threat to benthic macroinvertebrates and sewage spills were identified as a potential threat to fish communities. Sediments were analysed for pesticides, heavy metals, petroleum hydrocarbons and nutrients and sediment toxicity was assessed using *Chironomus tepperi* and toxicity identification evaluation. The gastropod *Potamopyrgus antipodarum*, the Poeciliidae *Gambusia holbrooki* and goldfish ( *Carassius auratus*) were examined to determine whether there was evidence of exposure to endocrine disrupting chemicals. A variety of pollution point sources were found, ranging from heavy metals, synthetic pyrethroids and fungicides. Toxicity identification evaluation tests confirmed that organic and heavy metal pollution contributed to sediment toxicity. Sewer spills did not appear to impact fish communities compared to those present in the rural headwaters of the creek. This study provides clear information to assist environmental managers understand what are the priority pollution issues that need to be addressed to protect aquatic ecosystems.

**HM02B-5**

**Biodegradation of non-steroidal antiinflammtory drugs (NSAIDs) and their non-halogenated analogs in nitrifying batch reactors**

V Osorio[1], SP Pérez[1], DB Barceló[2]
[1]IDAEA-CSIC, BARCELONA, Spain
[2]ICRA, GIRONA, Spain

The non-steroidal anti-inflammatory drugs (NSAIDs) have received considerable attention by the scientific community due to frequent detection in monitoring surveys on sewage-impacted surface waters, associated with high consumption rates and low removal efficiencies during conventional activated sludge treatment (AST) in WWTPs.Despite the interest in the fate of these polar compounds in engineered and environmental systems, it has been marginally considered. Little evidence has been published as regards metabolic pathways in microbial communities like those encountered in the aeration tank of the AST. Previously, nitroso (TP324) and nitro (TP340) compounds of diclofenac (DCF) were identified.Given the potential ecotoxicological risks of nitrated derivatives, the production of these compounds is an environmentally relevant matter of concern.This study aimed to investigate uncovered aspects in environmental fate in WWTPs of the NSAIDs:DCF, meclofenamic,flufenamic and tolfenamic acids, and lumiracoxib. Biodegradation experiments were performed under controlled laboratory settings in order to gain further insight into the biodegradability and metabolic pathways of these compounds.Samples from the biodegradation studies were screened for the presence of stable intermediates and these were characterized by hybrid quadrupole-time of flight (QqToF)-MS in combination with H/D-exchange experiments leading to the discovery of unusual microbial transformation products.To evaluate the biodegradability of target compounds, the structurally related compound 2-anylinophenylacetic acid (APAA) was used.Biodegradation experiments in batch-reactors loaded with mixed liquor demonstrated that degraded faster than DCF. After one day, 50% of APAA (228 Da) was degraded and the formation of one transformation product was confirmed. Structure elucidation by means of ultra performance liquid chromatography-electrospray ionization-hybrid quadrupole-time of flight-mass spectrometry in conjunction with H/D-exchange experiments identified it as deriving from nitrosation of the hydroxyl group in the carboxylic acid moiety (256 Da).Although the contribution of nitrifying bacteria to the biomass in the mixed microbial community of the AST tank in WWTPs is less than 5 %, the operational conditions of the lab-scale reactors were favorable for the growth of nitrifiers in terms of oxygen supply, and temperature and pH of the mixed liquor.

**Post-ozonation in a municipal wastewater treatment plant improves water quality in receiving stream as indicated by the abundance of species at risk**

R Ashauer
Eawag, DÜBENDORF, Switzerland

Removal of organic micropollutants from wastewater by post-ozonation has been investigated in a municipal wastewater treatment plant (WWTP) upgraded with ozonation, followed by sand filtration, as an additional treatment step of the secondary effluent. Here, the SPEAR (Species At Risk) indicator was used to analyse macroinvertebrate abundance data that was collected in the receiving stream to investigate whether ozonation followed by sand filtration improved the water quality. Before ozonation no significant difference between upstream and downstream SPEARpesticides could be observed. During ozonation the SPEARpesticides values indicate a better water quality downstream of the WWTP. There are 9% more vulnerable species present in the downstream samples. The comparison of the downstream macroinvertebrates before ozonation with those during ozonation exhibits an even clearer improvement of the water quality through ozonation (13% more vulnerable species). The SPEAR concept, originally developed to indicate pesticide stress, also appears to indicate toxic stress by micropollutants other than pesticides. The responsiveness of the SPEARpesticides indicator does not necessarily mean that the stressors are pesticides; rather it means that those macroinvertebrates that are vulnerable to pesticide pollution are also vulnerable to pollution by micropollutants from WWTPs. The change in SPEAR in the macroinvertebrate community downstream the WWTP indicates that toxicity by pollutants decreased by more than one order of magnitude during ozonation. Ozonation followed by sand filtration has favourable impacts on the composition of the macroinvertebrate community which indicates a significant and relevant improvement of the water quality in the receiving stream.

## HM03 - Integrated long term monitoring as a tool for the global assessment of POPs

**HM03-1**

**5 Years of POP air monitoring in Germany: recent data from the air pollution monitoring network of the German Federal Environment Agency**

A Dreyer[1], C Temme[1], P Ebsen[1], E Bieber[2]
[1]Eurofins GfA, HAMBURG, Germany
[2]Federal Environment Agency, LANGEN, Germany

The directive 2004/107/EC requests indicative measurements of several polycyclic aromatic hydrocarbons (PAH) such as benzo(a)pyrene (BaP) at background sites. In Germany, these measurements are performed in the air pollution monitoring network of the German Federal Environment Agency (Umweltbundesamt, UBA). Additionally, these monitoring efforts are coordinated with the European Monitoring and Evaluation Programme of the UN/ECE (EMEP). Therefore, the UBA monitoring programme includes other persistent organic pollutants like polychlorinated biphenyls (PCB) or several organochlorine pesticides. Their routine determination started in 2007. Here, we will look back at 5 years of POP air monitoring in the UBA air pollution monitoring network. We will provide an overview about ambient air concentrations of selected POPs at four rural background monitoring sites in Germany (Zingst, Westerland, Schauinsland, Schmücke) and discuss them in terms of temporal and spatial variations. Challenges and difficulties encountered during the monitoring programme will be discussed in the presentation.

**HM03-2**

**Global-scale passive air sampling of legacy and emerging chemicals under the GAPS Network: recent progress and application of the 'integrated approach'**

T Haner, SC Lee, S Genualdi, M Koblizkova
Environment Canada, TORONTO, Canada

The Global Atmospheric Passive Sampling (GAPS) Network is the only global-scale program that contributes information on air concentrations of persistent organic pollutants (POPs) to the Global Monitoring Plan (GMP) of the Stockholm Convention on POPs. Under Article 16 (Effectiveness Evaluation) of the Convention, monitoring data for air is required to assess effectiveness of control measures on POPs and investigate their regional and global transport.
Quarterly sampling at more than 50 sites under the GAPS Network using polyurethane foam (PUF) disk samplers is now in its 6th year and has generated the first ever global data set of POPs in air with seasonal resolution. This includes polychlorinated biphenyls (PCBs) and organochlorine pesticides (OCPs, e.g. a-HCH, g-HCH, chlordanes, endosulfans). The availability of this type of data has contributed to an 'integrated approach' to understanding chemical sources, fate and transport. This involves integrating measurement data with transport models and emissions inventories.
A pilot study completed in 2009 tested a new type of PUF disk sampler that is impregnated with XAD to increase its sorptive capacity, referred to as the sorbent-impregnated PUF or SIP-disk sampler. Co-deployment of PUF disk and SIP disk samplers at a subset of 20 GAPS sites has shown good agreement between the two sampler types for PCBs. The SIP disk samplers also generated the first comparable, global-scale data for several classes of priority chemicals including polyfluorinated chemicals (PFCs), siloxanes, alternative flame retardants and current-use pesticides (CUPs).

**HM03-3**

**Assessing emerging organic pollutants in air in the Canadian Arctic and the Great Lakes regions**

HHN Hung[1], KA Brice[1], E Sverko[2], D Muir[1], C Teixeira[1], L Jantunen[1], N Alexandrou[1], K Su[1], M Shoeib[1], Y Su[1], H Xiao[1], P Fellin[3]
[1]Environment Canada, TORONTO, Canada
[2]National Laboratory for Environmental Testing, BURLINGTON, Canada
[3]AirZone One Ltd., MISSISAUGA, Canada

The Northern Contaminants Program (NCP) and the Integrated Atmospheric Deposition Network (IADN) conduct measurements of persistent organic pollutants (POPs) and other priority organic chemicals in the Canadian Arctic and the Great Lakes regions since the 1990s. Both programs have been actively screening for and adding new POPs and emerging organic pollutants to their target analyte lists in support of national and international control initiatives. An update on the long-term atmospheric trends of polybrominated diphenyl ethers (PBDEs) in air at the Canadian High Arctic station of Alert and at two Canadian IADN master stations, namely Point Petre and Burnt Island, will be presented. Preliminary time trends of four perfluorinated compounds measured at Alert indicate ubiquitous presence of these compounds in Arctic air. Recent air measurements of emerging pollutants, such as non-PBDE flame retardants (FRs) and current-use pesticides (CUPs) in these two remote regions imply long-range atmospheric transport potential of these compounds; indicating the need to further investigate their environmental fate and toxicity.

**HM03-4**

**Comparison of long-term trends in concentrations of persistent organic pollutants in ambient air derived from passive and active sampling techniques.**

J Klanova[1], J Komprda[1], P Cupr[2], J Kohoutek[1], R Prokes[1], I Holoubek[1]
[1]Masaryk University, BRNO, Czech Republic
[2]Masaryk university, BRNO, Czech Republic

The Global Monitoring Plan (GMP) is an activity developed under the Stockholm Convention (SC) on Persistent Organic Pollutants (POPs) with a purpose of providing a tool for effectiveness evaluation of the SC measures. First global assessment of current baseline levels of POPs in core matrices (ambient air and human milk) was completed in 2008. Majority of data on ambient air levels of POPs was collected using the passive air samplers (PAS). Even though passive samplers only provide semi-quantitative information on the atmospheric pollution, they still offer a valuable tool to study spatial and temporal variability of the POP levels in the atmosphere. Such data are very valuable when it comes to assessments of the fate of persistent compounds in the environment - thein cycling between compartments, long-range transport or accumulation in various matrices - as well as for the validation of various distribution and transport models.
In 2009, the Conference of the Parties of the SC decided that levels of POPs in core matrices will be assessed every six years. Question remains whether the six year period proves to be sufficient for establishment of the trends, and whether these trends will correlate with those derived from conventional high volume sampling.
Observatory of the Czech Hydrometeorological Institute in Košetice is a site where background POP monitoring program of the European Monitoring and Evaluation Program (EMEP) has been active since 1988. Simultaneous employment of PAS and high volume samplers at this site since 2003
provides necessary information on the performance of passive samplers and allows for intercalibration of these two techniques. At the same time, it is the only site with the history of six years of on-going monthly PAS measuremens where the observed temporal trends can be compared to the long-term trends derived from two decades of continuous ambient air monitoring using the high volume air samplers.

**HM03-5**

**Twenty years of monitoring of persistent organic pollutants in the United Kingdom: sources, fate and time trends.**

A Katsoyiannis, R Gioia, AJ Sweetman, KC Jones
Lancaster University, LANCASTER, United Kingdom

The Centre for Chemical Management (CCM) in Lancaster, under the support of the Department for Environment, Food and Rural Affairs (DEFRA) has been running a long-term air monitoring program in the UK called TOMPs (Toxic Organic Micro Pollutants), since the beginning of the 1990s. In the frames of this project, air samples (gas and particulate phases) have been collected from a number of urban and rural/semirural areas and analysed for PCBs, PAHs, PCDD/Fs and PBDEs.
The occurrence of the afore-mentioned chemicals throughout these two decades, the changes in their levels and their fate are investigated. Various widely accepted tools like the PAH molecular diagnostic ratios, isomers and congeners profile analysis and other statistical approaches are used to reveal sources and seasonal variations
The atmospheric concentrations are compared with existing emission inventories and the latter are evaluated.
The results throughout these two decades are absolutely comparable, because the same methods/techniques have been used and clearly these results constitute one of the longest time series ever published.

**HM03-PS**

**Poster spotlight: Monitoring POPs in different matrices**

Miscellaneous

Poster spotlight highlighting abstracts WE 206, WE 207, WE 208, WE 209:
- Sampling rates when measuring gas phase POPs air concentration with passive air samplers.
- Monitoring the continental and intercontinental background of persistent organic pollutants in Africa
- Are the Mt. Qomolangma regions in Himalayas (Nepal) really remote areas for persistent organic pollutant contamination?
- Long-term trends of POPs in human milk in Czech Republic

## HM04 - Sorption and bioavailability of organic chemicals: mechanisms relevant for toxicity and bioremediation

**HM04-1**

**PAH extraction recovery from granular activated carbon**

MI Rakowska, D Kupryianchyk, AA Koelmans, T Grotenhuis
Wageningen University, WAGENINGEN, The Netherlands

River and marine sediments are contaminated with a wide variety of hydrophobic organic compounds (HOC), which are persistent and tend to concentrate as they further proceed in the food chain. Currently, a new risk based approach accomplished by measures of freely dissolved pollutants in the pore water is in focus of international research. It has been shown that the fraction of HOCs that desorbs sufficiently fast and equilibrates to the freely dissolved concentration in the pore water is more relevant for risks to aquatic biota, than the total concentration in the sediment. In the past years many studies demonstrated the potential of activated carbon (AC) amendments for sediment associated organic pollutants and thus availability reduction. Whereas activated carbon already has been applied to immobilize HOCs in bed sediments, not that much attention has been dedicated to granular activated carbon. We therefore conducted experiments where GAC was used to concentrate aqueous phase PAHs from sediment-water slurries. Polluted GAC was further used for testing different solvent (mixtures) and extraction techniques for the recovery studies of bound PAHs.

**HM04-2**

**Effect of the soil amendments activated charcoal, biochar and compost on desorption and biodegradation of phenanthrene**

G Marchal[1], KEC Smith[1], A Winding[1], LW de Jonge[2], UG Karlson[1]
[1]NERI - Aarhus University, ROSKILDE, Denmark
[2]DJF, TJELE, Denmark

Soil and groundwater remediation is aimed at reducing levels of pollutants to below regulatory thresholds. Polycyclic aromatic hydrocarbons (PAHs) are an important class of soil pollutants. Often, a large portion of the PAHs are degraded by soil microorganisms within short times (<100 days), and this is often followed by slower degradation, resulting in a non-degradable residual fraction.
Soil amendments such as activated charcoal (AC), biochar and compost can reduce the aqueous concentration of PAHs. On the one hand this might limit the bioavailability and uptake by organisms leading to reduced toxicity, but on the other hand this might also decrease biodegradation.
This study investigated the abiotic desorption of [9-$^{14}$C]phenanthrene, as a model PAH, from the three soil amendments, and compared this to the biodegradation of the sorbed phenanthrene. The total abiotic desorption of phenanthrene from the soil amendments in different sterile aqueous solutions (MilliQ water, fertiliser and broth) to an infinite silicone sink was measured. The total amount of phenanthrene desorbed was 12 to 46% for AC, 66 to 86% for biochar and 98% for compost, with higher desorption in the presence of broth.
This was compared to the biodegradation of phenanthrene sorbed to the soil amendments in fertiliser and broth by *Sphingomonas* sp (DSM 12247). Phenanthrene was completely degraded in all the soil amendment suspensions, and the total amount mineralized was 43 to 75 % for AC, 50 to 82% for biochar and 56 to 74% for compost, with higher mineralization in the presence of fertiliser.
Therefore, a low abiotic desorption of phenanthrene (as with the AC) does not lead to a low biodegradation. Our results suggest that adding soil amendments to contaminated soil can reduce phenanthrene mobility without affecting the biodegradation and mineralization.

**HM04-3**

**Dispersal networks for enhancing bacterial degradation under heterogeneous environmental conditions**

T Banitz, LY Wick, K Frank, I Fetzer, H Harms, K Johst
Helmholtz Centre for Environmental Research - UFZ, LEIPZIG, Germany

Successful bioremediation of organically polluted soil sites depends on the bioavailability of pollutants to catabolically active microorganisms. In particular, the heterogeneity of environmental conditions often limits bacterial access to pollutants. Experimental and modelling studies revealed that fungal networks can facilitate bacterial dispersal and may thereby improve pollutant bioavailability. Here we investigate the influence of such bacterial dispersal networks on biodegradation performance under spatially heterogeneous abiotic conditions using a process-based simulation model. To match situations regarded as being typical in polluted soils, two types of abiotic conditions are studied: heterogeneous bacterial dispersal conditions, i.e. a mix of areas where bacterial movement is efficient or restricted, and heterogeneous initial resource distributions, i.e. a mix of areas with high or low pollutant concentrations. Under these conditions, the simulation model predicts that networks facilitating bacterial dispersal can enhance biodegradation performance for a wide range of spatial heterogeneities. Additionally, the time horizon over which this performance is assessed and the networks' spatial configuration are key factors determining the degree of biodegradation improvement by dispersal networks. Our simulation results strongly support the idea of stimulating the establishment of fungal mycelia for enhanced bioremediation of polluted soils.

**HM04-4**

**A self-dying reporter bacterium determining the bioavailable fraction of phenanthrene in soil**

D Shin, K Nam
Seoul National University, SEOUL, South-Korea

When a hydrophobic organic pollutant is released to soil, sorption/desorption is the most important process for the bioavailability and toxicity of the compound. With time, the contaminant would migrate into hydrophobic organic matter phase, and its bioavailability and toxicity may decrease. If a remedial goal is established based on the total extractable concentration of the contaminant in the contaminated site, the risk and the expenses may be overestimated and dissipated. Therefore, the assessment of the bioavailability and toxicity of an organic pollutant in soil seems to be worthwhile for setting up the reasonable remedial plan. The aim of the present study is to investigate the performance and feasibility of a self-dying reporter bacterium visualizing and quantifying the bioavailability and toxicity of phenanthrene in soil. Time-dependent aging phenomenon of the contaminant in soil was also considered. A self-dying reporter bacterium harboring a cell-killing gef gene (named strain S) was designed to die and lose its green fluorescence on the initiation of phenanthrene degradation. To analyze the aging effect of phenanthrene in soil by the reporter bacterium, phenanthrene-spiked soil was incubated for 18 months and the fluorescence response of the reporter bacterium was measured. No significant change was observed in strain S with Ottawa sand with the increasing aging time, while the reporter's response in soil drastically changed after 3 months. The available fraction measured by the other physico-chemical methods (i.e., hydroxypropyl-beta-cyclodextrin extraction and desorption with Tenax bead) tended to overestimate the availability of phenanthrene in soil. Our data show that the reporter bacterium determines the living organism-based availability and toxicity, which are based on the interaction between phenanthrene, soil, and bacterium. In conclusion, the residual toxicity and bioavailability in soil with increasing aging time and the soil properties was able to be visualized and quantified by using the novel reporter bacterium developed in this study. In addition, comparing the strain S to a traditional reporter bacterium, the strain S has better resolution and feasibility to soil. This study supports the potential of the reporter strain for applications in the visual monitoring of the bioavailable phenanthrene and real risk in contaminated sites. It can also be applied to set a risk-based cleanup level and a contaminant site management plan.

**HM04-5**

**Sorption of phenolic acid anions by black carbon is accompanied by release of hydroxide into solution**

J Pignatello[1], J Ni[2]
[1]Connecticut Agricultural Experiment Station, NEW HAVEN, United States of America
[2]College of Geographical Sciences, Fujian Normal University, COLLEGE OF GEOGRAPHICAL SCIENCES, China

Black carbon occurs naturally in soils, and certain types of engineered carbons, such as biochar and activated carbon, have been considered for their potential to enhance soil fertility or reduce the bioavailability of soil contaminants. While adsorption of hydrophobic compounds to black carbon has been studied intensively, little attention has been paid to ionizable compounds which are common among the myriad of natural and synthetic compounds that come into contact with soil. We studied the sorption of cinnamic and coumaric acid anions by commercial biochar prototypes. These compounds belong to the class of plant root exudates known as "phenolic acids"that play important roles in agricultural and ecological dynamics as allelopathic agents. Their structures also represent some of the aromatic substructures of humic and fulvic acids, which are well known to adsorb to black carbon surfaces. Cinnamic and coumaric acids (pKa 4.4 and 4.7, respectively) are appreciably ionized in soil pore water at ordinary pH values. We focused on conditions favoring the anion. Sorption in phosphate-buffered systems at pH 6.9 was highly nonlinear and trended with the specific surface area of the biochar. Sorption is remarkably strong: the Kd (Cs/Cw; L/kg) values, which ranged from 500-40000 depending on biochar and phenolic acid concentration, are several orders of magnitude greater than the corresponding calculated octanol-water partition coefficient (Kow) of the organoanions (0.38 and ~ 0.1 L/L, respectively). Sorption was unaffected by Ca2+ or Mg2+ up to 0.1 M, ruling out an influence of surface charge or the involvement of bridging of carboxylate groups by metal ions. Isotherms in pH 6.9 buffered and non-buffered systems diverge as phenolic acid loading increases, the non-buffered showing reduced sorption relative to the buffered system. Accompanying loading in the absence of buffer is an increase in the pH, indicating that adsorption of the phenolic acid takes place simultaneously with the release of hydroxide ions into solution: $RCO_2^-$ + H2O + BC --> $(RCO_2^-(H^+)$-BC + $OH^-$ . This represents a novel mechanism for sorption of carboxylate ions and has significant implications for natural and synthetic entities (molecules or substructures) having a pKa in an intermediate range (e.g., 3-8). A possible driving force is the hydrophobic effect of the undissociated acid, which may be strong enough to overcome the unfavorable energy required to ionize water.

**HM04-6**

**How to model the sorption affinity of cationic organic compounds in natural organic matter?**

STJ Droge, KU Goss
UFZ - Helmholtz Centre, LEIPZIG, Germany

Using a highly consistent experimental data set for 70 compounds, we examined how the molecular structure of organic cations affects the sorption affinity to natural organic matter (NOM). Positively charged organic compounds, such as cationic surfactants, fluoxetine (prozac) or methamphetamine, are sorbed to negatively charged sites in NOM. This sorption process occurs mainly through an ion-exchange process with other sorbed cations, such as sodium or calcium. Previous studies and our recent work showed that the affinity of organic cations for NOM increases (i) if salt concentration decrease, and (ii), for organic cations with larger nonpolar side chains. Thus, the ion-exchange affinity of organic cations on NOM involves both ionic and nonionic interactions. For a proper risk assessment of organic cations, it is highly desirable to predict the influence of ionic and nonionic interactions from the molecular structure. Testing sorption at controlled pH and ionic strength creates constant influence of ionic interactions. Remaining differences between organic cations will then be related to differences in nonionic interactions. The observed differences in ion-exchange affinities for organic cations are not explained by calculated differences in octanol-water distribution coefficients (Kow), as recently proposed in risk assessment procedures. Other single-parameter regressions also appear to be unsuccessful. We demonstrate that multiparameter models can, as far as we studied, at best partially explain differences in sorption affinity between compounds, because the selection of the suitable descriptive molecular parameters is highly challenging. New insights in the ion-exchange affinity of organic cations and advanced sorption models are highly needed for further improvement of risk assessment procedures.

## LC01 - Developments in Life Cycle Impact Assessment (LCIA)

**LC01A-1**

**Fate modelling of chemical compounds with incomplete data sets**

M Birkved[1], R Heijungs[2]
[1]Technical University of Denmark, KGS. LYNGBY, Denmark
[2]Institute of Environmental Sciences (CML), Leiden University, LEIDEN, The Netherlands

Impact assessment of chemical compounds in Life Cycle Impact Assessment (LCIA) and Environmental Risk Assessment (ERA) requires a vast amount of data on the properties of the chemical compounds being assessed. These data are used in multi-media fate and exposure models, to calculate risk levels and other indicators. ERA typically addresses one specific chemical, but in an LCIA, the number of chemicals encountered may be quite high, up to hundreds or thousands. This study explores the development of meta-models, which are supposed to reflect the "true"multi-media fate and exposure model in an approximate way. The idea is that not all data needed in a multi-media fate and exposure model are completely independent and equally important, but that there are physical-chemical and biological relationships between sets of chemical properties. A statistical model is constructed to underpin this assumption, and to provide simplified proxies for the more complicated "real"model relationships.
In the presented study two approaches for the reduction of the data demand associated with characterization of chemical emissions in USEtox™ are tested:
The first approach yields a simplified set of mode of entry specific meta-models with a data demand of app. 63 % (5/8) of the USEtox™ characterization model.
The second yields a simplified set of mode of entry specific meta-models with a data demand of 75 % (6/8) of the original model.
The results of the study indicate that it is possible to simplify characterization models and lower the data demand of these models applying the presented approach. The results further indicate that the second approach relying on 75 % of the original data set provides the meta-model sets which best mimics the original model. An overall trend observed from the 75 % data demand meta-model sets, is that except for fate factors covering the route from soil emission (natural and agricultural soil) to aquatic compartments, good correlation between the predicted fate factors (derived from the meta-models) and the observed fate factors (modeled in USEtox™) are obtained. The regression coefficients obtained for the predicted fate factors plotted against the observed fate factors, excluding the fate factors covering the route from emission to soil to aquatic compartments, were all in the range 0.6818≤ R2 ≤0.9470

**LC01A-2**

**Variability and spatial distribution of chemical's removal rates: implication for spatial resolution within Life Cycle Impact Assessment**

S Sala, D Marinov, D Pennington
Joint Research Center European Commission, ISPRA (VA), Italy

Spatial differentiation is a topic of increasing interest within Life Cycle Impact Assessment (LCIA). A key issue to be addressed in the LCIA methods, models and corresponding characterisation factors is the level of spatial detail required and uncertainties related to the use of generic characterisation factors when the exact location of the activities is unknown. For ecotoxicity and human toxicity impact categories, some preliminary evaluations were done in order to assess the relative influence of substance properties and environmental parameters on the variability in the fate of chemicals in air, water and soil. In this work a methodology was developed as a guideline to decide the appropriate spatial resolution to address the environmental fate as first step of impact assessment of chemicals. The methodology was tested on a set of 34 representative organic chemicals, clustered according to their physical and chemical properties. The test set took into account chemicals having a large diversity of properties in order to be representative, as far as possible, as well as their potential differences in the environmental fate.

**LC01A-3**

**Development of a new modelling framework to address issues of metal fate and effects in LCIA**

N Gandhi[1], MAJ Huijbregts[2], D van de Meent[3], WJGM Peijnenburg[3], J Guinée[4], ML Diamond[1]
[1]University of Toronto, TORONTO, Canada
[2]Radboud University, NIJMEGEN, The Netherlands
[3]National Institute of Public Health and the Environment (RIVM), BILTHOVEN, The Netherlands
[4]Leiden University, LEIDEN, The Netherlands

Life Cycle Impact Assessment (LCIA) models currently estimate fate and toxicity assuming that all dissolved metal species are equally bioavailable and can cause toxicity in ecological receptors. This treatment of metals, similar to organic chemicals, introduces a significant error mainly because of metal speciation and non-degradability that affect their bioavailability and fate. The goal of our project was to incorporate state-of-the-art science into a consistent, generic framework for adjudicating chemical hazard with a view to addressing the criticisms raised for metals.
We recently proposed a new modelling framewok that introduced a Bioavailability Factor (BF) to the calculation of Comparative Toxicity Potential (CTP) for use in Life Cycle Impact Assessment (LCIA). The method uses (1) USEtox for environmental fate, (2) WHAM 6.0 for metal partitioning and speciation in aquatic systems, and (3) Biotic Ligand Model (BLM) for calculating average toxicity or Effect Factor (EF). We also proposed to apply modified Free Ion Activity Model (FIAM) to calculate EFs for metals for which Biotic Ligand Models are not available. While arriving at a set of CTPs, we explored the sensitivity of factors like variability in the chemistry of receiving environment on metal fate and toxicity. We showed the implications of choosing a watertype by applying the model to Cu, Ni and Zn for 100 frehswater systems of world's largest lakes and rivers with varying aquatic chemistry. Results of model applications consistently showed that the greatest contributor to variability in CTP was BF followed by EF. A large range of ~4 orders-of-magnitude in estimates of BFs and EFs often changed the relative hazard of metals based on numerical ranking of CTPs. However, the current LCIA practice has been to use generic environmental data to typify a single "evaluative environment."To address this issue, we then analyzed the individual effects of water chemistry parameters, such as pH, DOC and hardness, to derive generic freshwater archetypes to be used in LCIA.
The successful outcome of this project is a new modelling framework for metals, which is consistent with that for organic chemicals, to provide equal and fair evaluation of environmental impacts of their emission. We report a large range of individual metal CTPs that relate mainly to variability in ambient chemistry or archetypes.

**LC01A-4**

**Comparison of metal toxic impacts between aquatic and terrestrial organisms: is the free ion concentration a sufficient descriptor?**

M Owsianiak, RK Rosenbaum, HF Larsen, MZ Hauschild
Technical University of Denmark, KGS. LYNGBY, Denmark

Characterization of metal toxic impacts in comparative risk assessment and life cycle impact assessment (LCIA) should take into account metal speciation and interactions with soil/water organic constituents, because these mechanisms control metal bioavailability and may influence their toxic properties. In a comparative context we are faced with the need to characterise thousands of substances, but the limitation of the available data calls for reliable indicators suitable for extrapolation from the limited data that is available. Indeed, free metal ion concentration has in some cases been shown to be a sufficient indicator of metal toxicity for both aquatic and terrestrial species. With the aim of deriving extrapolations to predict terrestrial toxic impacts of metals from aquatic effect data, we compared copper toxicity of aquatic organisms with that of terrestrial organisms, testing the hypothesis that the free metal ion is an appropriate "general"descriptor of metal toxicity.
Results for 128 laboratory tests on Daphnia magna exposed to copper ions (Cu2+) in water show that variation of several orders of magnitude are observed between the toxicity tests. These variations may be a result of the inability of the free metal ion concentration to reflect toxicity, as the presence of protons and other cations reacting with biological binding sites has been shown to affect the toxicity of copper to D. magna. Similar patterns, albeit with smaller variations, are observed for terrestrial organisms. Up to three orders of magnitude difference occur for the extreme case of barley (Hordeum vulgare).
Given the scarcity of terrestrial effect data compared to aquatic data, reliable and transparent, mechanistic-based predictions of terrestrial toxic impacts from aquatic effect data would be an important step ahead in the context of LCIA or comparative risk. Here we demonstrate that the overall ability of the free metal ion to reflect toxicity of metals for aquatic and terrestrial organisms is limited. This has consequences if potential terrestrial toxic effects are based on extrapolations from aquatic data, because the use of more sophisticated models such as the Biotic Ligand Model (BLM) would be required. However, extrapolation models based on an improved free ion approach might still be a good proxy, particularly when the comparative nature of life cycle assessment is taken into account.

**LC01A-5**

**Including ecotoxic effects on warm-blooded predators in life cycle impact assessment**

L Golsteijn[1], R Zelm, van[1], K Veltman[2], G Musters[1], AJ Hendriks[1], MAJ Huijbregts[1]
[1]Radboud University, NIJMEGEN, The Netherlands
[2]NTNU, TRONDHEIM, Norway

In current Life Cycle Impact Assessment (LCIA) of ecotoxicity the focus is on cold-blooded species. This paper describes a method to calculate Characterization Factors (CFs) for the assessment of potential toxic impacts of chemical emissions on warm-blooded predators in freshwater food chains. The method was applied to 329 organic chemicals. The CF for warm-blooded predators was defined as a multiplication of the chemical-specific Fate Factor (FF), Exposure Factor (XF), Bioaccumulation Factor (BF), and Effect Factor (EF). FFs and XFs were calculated with the multimedia fate and exposure model USES-LCA 2.0. BFs were calculated with the bioaccumulation model OMEGA, for chemical uptake via fresh water, food and air. EFs were calculated based on median lethal doses (LD50-values), obtained from literature. The chemicals' Concentration Built-up (CB, i.e. the product of FF, XF, and BF, summed for the different routes of exposure) showed a range of 7 to 9 orders of magnitude, depending on the emission compartment. EFs displayed a range of 7 orders of magnitude. Characterization factors ranged 8 orders of magnitude for an emission to rural air, fresh water, and agricultural soil. The contribution of the different uptake routes to CB were 1% (90%-CI 0-2%) for uptake via air, 43% (90%-CI 11-50%) for uptake via water, and 56% (90%-CI 49-87%) for uptake via food, after emissions to fresh water. Uptake via air was mainly relevant for emissions to air (on average 42% with 90%-CI 5-98%). Our results showed that the chemicals' CB were positively correlated with their Kow, irrespective of the emission compartment. In conclusion we can say that we were able to calculate CFs for the impact of toxic emissions on ecosystems. Uptake via air, fresh water, and food may all be relevant, depending on the emission compartment and the properties of the chemical. The inclusion of biotransformation was highly relevant, but uncertain at the same time. The poster will further discuss the practical implications of our results for the assessment of toxic emissions in a life cycle context.

**LC01A-6**

**LCA of contaminated site remediation - integration of site-specific impact assessment of local toxic impacts**

G Lemming[1], MZ Hauschild[1], J Chambon[1], G Manoli[1], PJ Binning[1], C Bulle[2], M Margni[2], PL Bjerg[1]
[1]Technical University of Denmark, LYNGBY, Denmark
[2]CIRAIG, MONTREAL, Canada

The environmental impacts from remediation can be divided into primary and secondary impacts. Primary impacts cover the local impacts associated with the on-site contamination, whereas the secondary impacts are impacts on the local, regional and global scale generated by the remediation activities. Although two different remediation methods reach the same remedial target with time, their timeframes can be substantially different and lead to a difference in the local toxic impacts over time. By including primary impacts in the LCA of remediation this quality difference is accounted for.

Primary impacts have typically been assessed using site-generic characterization models representing a continental scale and excluding the groundwater compartment. Soil contaminants have therefore generally been assigned as emissions to surface soil or surface water compartments. However, such site-generic assessments poorly reflect the fate of frequent soil contaminants such as chloroethenes as they exclude the groundwater compartment and assume that the main part escapes to the atmosphere. Another important limitation of the generic impact assessment models is that they do not include the formation of metabolites during biodegradation of chlorinated ethenes, of which particularly vinyl chloride is problematic due to its toxic and carcinogenic effects. In this study, the assessment of local toxic impacts with the USEtox model was therefore combined with site-specific reactive transport modeling of the contaminant mass discharge to groundwater. The exposure via contaminated groundwater was subsequently estimated using exposure parametres representing the local groundwater body.

The developed methodology for a site-specific impact assessment of primary impacts is tested on two case localities contaminated with chlorinated solvents. Secondary and primary impacts of a number of remediation options for the two sites are evaluated and compared. The results show that especially vinyl chloride, which is an intermediate product during biodegradation of trichloroethene, contributes significantly to the human toxicity of bioremediation scenarios (86-98 % of the human toxicity impacts at Site 1). The inclusion of primary impacts in the environmental assessment of remediation alternatives gives a more complete basis for comparison of technologies with substantially different timeframes and efficiencies.

**LC01B-1**

**Classification of pollutants into emission based impact categories : a site specific conceptual frame**

A Ventura
Laboratoire Central des Ponts et Chaussées, BOUGUENAIS CEDEX, France

The classification step is systematically neglected in the calculation of LCIA indicators: for several direct contribution of one pollutant to several impact categories, the distribution between these impact categories is not accounted. The proposed approach of a non-redundant classification is based on the probability that an emitted substance and its chemically degraded forms are involved into several environmental impacts.

The so-called zone classification is based on a classification coefficient alpha and requires categorization of chemical pathways (reactive, suspensive, direct, indirect). It is made of two steps: i) the first step requires defining an impacted zone around the source, inside which the emitted chemicals are expected to majorly diffuse or spread; ii) in the second step, the score of the chemical is set according to the occurrence of the chemical target inside the impacted zone.

The method is applied on a case study of NOx emissions in Paris. The choices of impacted zone and of chemical targets are discussed with the aim to meeting paradoxical constraints: local parameters must be sufficiently detailed in the majority of cases, but generic enough to avoid time consuming researches. The availability of data is also discussed as well as the possibility to include indirect impacts into the environmental system.

The conceptual frame suggested for classification of pollutants into emission-based impact categories, is a first approach for a scientific question that was raised in the 90's. It has important consequences in terms of data collection, system boundaries, and only practise will show its actual feasibility.

**LC01B-2**

**Toward consistent Emergy calculations with LCI databases: perspectives on characterization factors**

B Rugani[1], S Bastianoni[2], E Benetto[1], L Tiruta-Barna[3]
[1]Public Research Centre (CRP) 'Henri Tudor', ESCH-SUR-ALZETTE, Luxembourg
[2]Ecodynamics group, Dept. Chemistry, University of Siena, SIENA, Italy
[3]INSA Toulouse-LISBP, TOULOUSE, France

Emergy, a method developed by Howard T. Odum during the eighties, is defined as the quantity of energy (usually solar energy, calculated in solar em-joules; i.e. seJ) directly and indirectly necessary to support a given system and its level of organization. It provides a measure of the global natural efforts required (i.e. memorized) to make a product or service available. Its boundaries of calculation can be very large, including for instance many of the ecosystem services not captured, at present, by other life cycle oriented approaches. Aim of this work was to develop a consistent set of characterization factors that may enable for a comprehensive calculation of emergy in the Ecoinvent LCI database. These factors are identified in Unit Emergy Values (UEVs) of primary natural resources (e.g. mineral, metal, fossil, water, etc.), and are calculated in MJse/unit of resource (e.g. MJse/kg, MJse/MJ, MJse/m3). In conventional emergy evaluations, a starting reference baseline, represented by the sum of solar, tide, and Earth deep heat energies (annual emergy budget; e.g. 9.44E24 seJ/yr), is used to estimate the average annual emergy flows of wind, water, and land systems, and therefore all other resource and product UEVs in cascade. This traditional approach (i.e. 'top-down') presents several sources of uncertainty. We propose here a uniform 'bottom-up' procedure that may allow for a more consistent quantification of primary resource UEVs. In this case, only strictly necessary quantities of sun, tide, and deep heat energies are directly and independently included in natural resource productions. Results, in particular for fossil resources (i.e. gas, oil, coal), showed that 'bottom-up' based-UEVs are slightly higher than previous 'top-down' based-ones, due to an increase of calculation details. Advances have been made in re-calculating UEVs for a larger number of Ecoinvent elementary flows (e.g. for minerals, land occupations, biomasses). The 'bottom-up' approach should be further expanded to include all resource category groups, providing regionalized factors according to new LCI database versions possibly being available in the future. As discussed, re-calculating 'bottom-up'-based UEVs is one of the essential step toward a consistent implementation of the emergy method in LCA, giving added value to existing methods in the sphere of assessment for resource consumption and ecosystem quality.

**LC01B-3**

**The Water Impact Index: a stand-alone metric for water footprinting**

JB Bayart[1], E Aoustin[2]
[1]Veolia Environnement Recherche et Innovation, RUEIL-MALMAISON, France
[2]Veolia Environnement, PARIS, France

The decrease of freshwater resources availability is recognized as one of the major environmental issue of coming decades. Within Life-Cycle Assessment, several impact categories already aim to tackle impacts of entropic activities on water bodies, both from the quality aspect (i.e. aquatic ecotoxicity, eutrophication), but also from a quantity aspect. However, decision makers often have to deal with a high number of indicators, being environmental but also economical or social. Therefore, the number of environmental indicators considered by decision makers is often limited, leading to the avoidance of important environmental issues.

In order to reduce the number of environmental indicators related to freshwater aspects, the Water Impact Index: a "stand-alone"metric for assessing impact of entropic activities on freshwater resources has been developed. This indicator accounts for the reduction of freshwater availability for different users (both humans and ecosystems). For any product or process, the physical water balance is weighted by a quality index and a water stress index. This methodology is applied with a Life-Cycle thinking, taking into account both direct but also indirect water uses of any process. A case study on municipal water services shows how this indicator could be applied in order to help decision makers in a better understanding of water use impacts. Regarding drinking water production, the Water Impact Index is driven by direct water abstraction, as the quality of the resource used is very high. The sewage system contributes to reduce the Water Impact Index: the quality of wastewater collected is improved and brought back closer to environmental requirements. The study of different scenarios, such as overflows management solutions or potential water treatment processes improvements, has highlighted that the direct Water Impact Index could be easily decreased, with a low impact on indirect Water Impact Index. Finally, some crossed carbon footprint / Water Impact Index studies have shown that even if some change in water treatment solutions can lead to impact trade-off, some win/win solutions remain possible.

This study shows how some pieces of existing LCIA methodologies for assessing water use could be combined in order to create a simplified methodology to assess impacts of water use.

**LC01B-4**

**Urban-wide change in albedo: a multi-scale approach to LCA. The case study of New York City.**

T Susca[1], SR Gaffin[2], GR Dell'Osso[3]
[1]Polytechnic University of Bari and Columbia University, BARI, Italy
[2]Columbia University, NEW YORK CITY, United States of America
[3]Polytechnic University of Bari, BARI, Italy

In last decades the urban heat island phenomenon is becoming more frequent than in the past. The exposure to extreme temperatures is the primary cause of weather-related mortality in the United States especially among old people or people with social or physical vulnerability. Mitigation and adaptation strategies are necessary to reduce the impact of the extreme temperaures on human health. One of the possible mitigation strategy is the increase of the urban albedo.

Typically, the life cycle assessment (LCA) evaluation of a building components settled in urban contexts considers just partially the interactions between the components and the environment. In this study we considered the effects of the city-wide conversion of traditional black roofs into white roofs through the use of a LCA multi-scale approach. In a 'traditional' LCA approach the impact relative to the substitution of city-wide black roofs with white roofs would have been evaluated as the product of a functional unit white roof per the number functional units of roofs. Although this approach is widely applied it is not always able to explain the relationships between roofs and urban context. In this study we evaluated the avoided impact on human health due to the decrease of the summer temperatures obtained substituting the city-wide black roofs with white ones. The avoided damages on human health have been calculated using epidemiological data and considering an end-point approach to the LCA. The avoided deaths for heat strokes have been translated - through the use of statistical data - into Disability Adjusted Life Years (DALY). The total number of DALY has been divided per the number of square meters of white roofs, in order to have the equivalent amount of avoided impact on human health relative to each square meter of surface. The avoided impact on human health has been considered in the LCA evaluation of maintenance phase of a square meter of white roof. It has resulted that the avoided damages on human health determine a decrease by 69% in the final eco-score of a square meter of white roof. In this study we broadened the application of LCA to the urban context deepening the parameter albedo and we suggested a possible way to overcome some of the limits of the traditional LCA approach especially when it is applied to the building sector. Furthermore, this study provides useful information for decision-makers and policy-makers about environmentally preferable choices.

**LC01B-5**

**Including noise impacts on human health in LCA**

S Cucurachi[1], R Heijungs[1], K Ohlau[2], P Preiss[2]
[1]Institute of Environmental Sciences (CML), Leiden University, LEIDEN, The Netherlands

[2]Institute of Energy Economics and the Rational Use of Energy (IER), STUTTGART, Germany
Important methodological improvements are still needed for the development of characterisation models and factors to be used in LCA practice. In most cases the introduction of new impact categories would sensibly change the results of many completed LCA studies. LC-IMPACT three years' project focuses on the development and application of methods, characterisation and normalisation factors for categories not commonly included in life cycle impact assessment studies, taking the ILCD and SETAC/UNEP recommendations as a starting point. Our research within the project contributes to the development of a method for the inclusion of noise impacts on human health in LCA. To date, sound and noise are seldom present in LCI. Impact assessments have been conducted with regard to noise exposure. The few attempts available in the literature developed methodologies which are far from having the needed generalisation which would make them applicable to large systems, on a European or World level, or the flexibility for expanding them from a noise source (e.g. transportation noise) to another and from a subject (e.g. humans) to others. Our study aims at expanding from the knowledge acquired in the field of transportation noise, which seems to have attracted most of the research focus, to developing a method to include in LCA generic sources of noise which have a quantifiable impact on human health and which are of interest in the LCA practice.

**LC01B-6**
**Biome-specific effect factors for terrestrial acidification at the global scale**
LB Azevedo[1], R van Zelm[1], AJ Hendriks[1], R Bobbink[2], MAJ Huijbregts[1]
[1]Radboud University Nijmegen / Institute for Water and Wetland Research, NIJMEGEN, The Netherlands
[2]B-WARE Research Centre / Radboud University Nijmegen, NIJMEGEN, The Netherlands
Up to now, life cycle impact assessment (LCIA) does not encompass regionalized and global scale effect factors for terrestrial acidification. The major increases in acid deposition currently occur in soils that are not only the most sensitive to acidification but also the ones that hold the highest share of world's biodiversity. Thus it is important that LCIA is performed at the global scale. One of the outcomes of soil acidification is the decrease of soil pH. Given that the performance of plants depends on this soil property, changes in soil pH will affect plant diversity. This research consisted on an extensive literature review in which the potentially non-occurring fraction (PNOF) of plant species relative to soil pH was determined for the fourteen world biomes (e.g. tundra, deserts). The literature review yielded occurrence and non-occurrence data on over 5000 plant species; and 182 studies were included. Next, we computed biome-specific effect factors corresponding to changes in PNOF following a marginal change in soil pH. This study also considered the uncertainty of the effect factors within each biome. The results of this work provide regionalized biome-specific effect factors for terrestrial acidification at an endpoint level and at the global scale.

## LC02 - Developments in Life Cycle Sustainability Assessment (LCSA)

**LC02-1**
**Towards a life cycle sustainability assessment of products**
S Valdivia[1], AC Ciroth[2], GS Sonnemann[1], CU Ugaya[3], CA Alvarado[4], BL Lu[5], JF Fontes[4]
[1]UNEP DTIE, PARS, France
[2]GreenDelta TC, BERLIN, Germany
[3]UTFPR, PARANA, Brazil
[4]Pre, AMERSFOORT, The Netherlands
[5]Key Laboratory for Urban and Regional Ecology, Research Center for EcoEnvironmen, BEIJING, China
Taking the life cycle approach means going beyond the traditional focus on production site and manufacturing processes and including the environmental, social, and economic impact of a product over its entire life cycle. In order to put life cycle thinking into effective practice, the United Nations Environment Programme (UNEP) and the Society for Environmental Toxicology and Chemistry (SETAC) launched an International Partnership, the so-called 'Life Cycle Initiative'. The Life Cycle Initiative contributes to the 10-Year Framework of Programs in order to pursue Sustainable Consumption and Production (Marrakech Process). The Project Group of the Life Cycle Initiative on Social Life Cycle Assessment started its work in 2005. Following the completion of the UNEP Guidelines for Social LCA of products [1], this Project Group has the aim to interlink current LCA tools and provide a triple-bottom-line sustainable development toolbox.

**LC02-2**
**Life Cycle Costing - the second pillar in Life Cycle Sustainability Assessment (LCSA)**
W Kloepffer
LCA Consult & Review, FRANKFURT AM MAIN, Germany
Walter Klöpffer
LCA CONSULT & REVIEW, Frankfurt/M, Germany
Sustainability was adopted by the UN in Rio de Janeiro (1992) as the main political goal for the future development of humankind. It should also be the ultimate aim of product development. According to the well known interpretation of the original definition given in the Brundtland report, sustainability comprises three components: environment, economy and social aspects. These components or "pillars"of sustainability have to be properly assessed and balanced if a new product is to be designed or an existing one is to be improved.
For the environmental pillar there is already an internationally standardized tool (ISO 14040+14044: 2006): (Environmental) Life Cycle Assessment (LCA). Environmental Life Cycle Costing (LCC) is the logical counterpart of LCA for the economic assessment of products and Social Life Cycle Assessment (SLCA) for the social pillar. LCC surpasses the purely economic cost calculation by taking into account the use- and end-of-life phases and hidden costs. An LCC Code of Practice has been developed and recently published by SETAC. This code gives advise how to conduct an environmental LCC in accord with LCA. It is a very important point that different life-cycle based methods for sustainability assessment use consistent (ideally identical) system boundaries. This also includes the use of the physical life cycle in this "LCA type"LCC. Only in this case, LCSA can be defined and quantified according to the following general formula:
LCSA = LCA + LCC + SLCA
Weighting between the three pillars should be avoided so that an excellent economic performance cannot outweigh the environmental and social components. It should be noted that LCC is also a very useful stand-alone method for the estimation of the costs of a product over the whole life cycle. The full power of LCC is shown, however, in combination with LCA and SLCA.

**LC02-3**
**Economic material availability as a new area of protection for life cycle sustainability assessment**
L Schneider, M Berger, M Finkbeiner
Technische Universitaet Berlin, Dept. of Environmental Technology, BERLIN, Germany
The assessment of material use and availability is of major importance to secure future resource supply. Especially with regard to new vehicle concepts, resource questions are of increasing relevance as supposedly scarce metals are used.
So far, the utilization of resources along the life cycle of vehicles is assessed with indicators like primary energy demand and abiotic depletion potential. However, those indicators are usually dominated by the usage of fossil energy carriers. Materials which are commonly perceived as critical, like rare earth metals or lithium, do not contribute to the results of these indicators in a noticeable manner. The reason for this is that indicators like abiotic depletion potential only focus on geological extraction - reserve - ratios and partly use rather theoretical stocks like ultimate reserves (total material stock in the earth crust). Hence, they deliver no conclusion about the real availability or criticality of metallic resources.
In this work we introduce a new area of protection, the economic material availability. Several geological and economic criteria are identified and selected according to their potential and relevance for quantifying economic material availability. Different options for assessing these indicators are modeled and tested with regard to their usefulness and applicability within life cycle assessment.
In order to illustrate the effects of the new area of protection and the corresponding indicators, a comprehensive case study is accomplished. The life cycle inventory of a product from the automotive industry is assessed by means of conventional abiotic depletion potentials and the newly developed economic material availability indicators.

**LC02-4**
**Social LCA of an ecolabeled notebook**
J Franze, AC Ciroth
GreenDeltaTC, BERLIN, Germany
The demand for electronic products increases continuously, especially portable devices as laptops gain in popularity - irrespective of their impacts on environment and society. Computers are very complex products with global value chains: They are assembled in Asia, pre products come from Korea, Thailand, China, India, Mexico, or the Philippines, raw materials originate from all over the world. In addition, the majority of e-waste is recycled illegally in Asia or Africa. Strong competition moves the production of electronic devices and modules to low wage countries with low social and environmental standards, thus notebooks cause along their life cycle many negative environmental as well as social effects.
The presentation will focus on a study where we analyzed social, socio-economic, and also environmental impacts of an ecolabeled notebook of the Taiwanese company ASUSTeK, over its entire life cycle. The study was conducted from June until October 2010. The social and socio-economic impacts were modeled following the method of social LCA (S-LCA), according the UNEP/SETAC guidelines for S-LCA of products. The newly developed methodological sheets for the S-LCA method were considered as well.
We will present our modeling approach, the indicators / subcategories / stakeholder framework developed for the S-LCA, data sources for supply chain modeling and for assessing social and environmental impacts, practical problems in the modeling process, solutions, and also lessons learnt from the case study.
Considering methodological aspects is rewarding as we have conducted one of the first real case studies for social LCA; we will therefore report "how it was to apply the method".
Little explanation is probably needed on why it is interesting to look at the outcomes of the case study. With a consistent consideration of social and environmental impacts of a notebook over its entire life cycle, the case study is able to show hot spots for the environment and regarding social impacts that are related to the notebook. The study is also able to relate social benefits to environmental impacts. We will therefore present results of the case study, and of recommendations that can be derived, on a policy, company, and private consumer level.

**LC02-5**
**Societal perspective in S-LCA: a parallel to welfare maximisation in economic theory**
A Zamagni[1], P Buttol[1], O Amerighi[2], B Felici[2]
[1]ENEA, BOLOGNA, Italy
[2]ENEA - Ufficio Studi, ROMA, Italy
Social life cycle assessment (S-LCA), as defined in the UNEP/SETAC Guidelines [1], is increasingly emerging as a method for evaluating social performance of products/systems. The framework, which follows the LCA structure closely, does not pose limitations on the possible applications that might range from products to complex systems (e.g. single technologies or systems like waste management systems, etc.). The assessment is conducted from the perspective of different stakeholders, whose relevance is determined by the object and goal of the analysis. However, some critical points have been identified when the framework is applied to the evaluation of a (new/innovative) technology: what perspective should be adopted and, consequently, how the most appropriate indicators are identified.
In present applications, a company perspective is normally at the core of the method. Social impacts in S-LCA are related to the way a specific company manages social aspects of concern. Preliminary discussions by the authors highlighted that a company perspective should be left aside in favour of a societal one when a technology is the object of the analysis. The societal perspective should consider how the adoption of the technology would affect the social structure in which it will be embedded. To characterize the different perspective, the definition of a new stakeholder is proposed, which has foundations in economic theory

**LC02-6**
**Life Cycle Sustainability Assessment of multifunctional land-use systems: a consequential modelling approach**
MMR Brandão[1], R Clift[2], L Milà I Canals[3]
[1]European Commission, Joint Research Centre, ISPRA (VA), Italy
[2]Centre for Environmental Strategy, GUILDFORD, United Kingdom
[3]Unilever, BEDFORD, United Kingdom
Concerns over global climate change, decreased provision of ecosystem services and biodiversity loss have led to interest in using land in ways that mitigate these threats, particularly in using various forms of bioenergy to displace fossil fuels or to sequester carbon. In view of the competing

demands on land to feed people adequately, sustain biodiversity and ecosystem services and mitigate climate change, there is a clear need for a systematic basis for allocating land use with respect to economic and environmental objectives.
This study formulated an integrated environmental and economic assessment of the global consequences of changing current land use in UK with different land-use strategies for food, feed, fibre, fuel and carbon sequestration. Novel operational approaches are proposed for resolving methodological issues, and are applied in the characterisation of the main land-use strategies in the UK: diversion, intensification and extensification of existing cropland; and expansion onto set-aside and grassland. 224 scenarios were devised to reflect the different uses of the considered crops: wheat, oilseed rape, barley, sugar beet, Miscanthus, willow, and 9 forestry crops.
The results indicate that diverting food to either feed or fuel generally does not deliver improvements in all three criteria (i.e. of mitigating climate and biodiversity impacts, while creating extra economic value), but generally results in greenhouse gas (GHG) emission savings, mainly due to indirect land-use change (iLUC) effects.
Intensification in all land uses almost never saves GHGs. Conversely, extensification in all land uses almost always saves GHGs, but results in higher impacts to ecosystems. Expanding arable crops onto grassland never results in GHG savings, and only a few combinations of crops on set-aside will save GHGs. Only intensive strategies present Pareto improvements. Forestry crops always perform well. With very few exceptions, it is best to leave grassland untouched.
Expansion onto set-aside is undesirable by arable cropping, but desirable by energy and forestry crops. The former are best used for electricity whereas the latter as carbon sinks, even though no economic value is generated in the foreground system.

## LC03 - Increasing robustness of LCA methodology

**LC03-1**

**Development of product category rules for a sector environmental product declaration**

C Strazza, A del Borghi, M Gallo
University of Genoa, GENOVA, Italy

Systems for Type III Environmental Product Declarations (EPDs), relying on LCA methodology, are gradually becoming more known and operational on the market. Many industrial associations show growing interest on "product-type EPDs", in contrast to product specific EPDs. For this reason, the International EPD® system introduced a new feature, i.e. the Sector EPD. This tool shows a sort of average environmental profile of the product, based on the typical processing adopted in the local context and representative of the production offered by the sector. For this application, specific rules [Product Category Rules (PCR)] have to be issued to ensure comparability among different declarations within the same service group. The aim of the present study is to describe the particular choices in the development of PCR for a Sector EPD applied to cement production, as a case study.
PCR 2010:9 has been developed in order to define the requirements, based on environmental parameters, that should be considered in the LCA and EPD for the production of cement. The document was issued in an open and participatory process between companies and organizations having a good knowledge of the specific environmental aspects of the process.
Since the EPD is a concise document that outlines a simple profile of the environmental performances of a product, including objective, comparable and credible data, the definition of an appropriate methodology must be performed with particular rigour. The process of development of this methodology for a Sector EPD includes the definition of required data, data collection procedures, sample selection criteria, etc. The research highlights that a targeted analysis of the sample representativeness is required to support the robustness of the selection in view of the successive verification process. At the same time, some precise methodological choices have to be established in order to define the procedural criteria on the base of the transition from a product-specific to a product-type declaration. In this way, a sector EPD can find application in the use as a sector bench-mark for separate producers manufacturing or offering products and services in the same product category. It can also be used as a guidance tool indicating the general environmental performance of a product category, i.e. for planners, designers and architects in the construction sector not needing information from specific products from selected suppliers.

**LC03-2**

**Assessing temporary carbon sequestration and storage with dynamic LCA**

A Levasseur[1], P Lesage[1], M Margni[1], M Brandão[2], R Samson[1]
[1]CIRAIG - École Polytechnique de Montréal, MONTRÉAL, Canada
[2]Institute for Environment and Sustainability, JRC, European Commission, ISPRA, Italy

Life cycle assessment (LCA) is a preferred tool to assess greenhouse gases (GHG) mitigation projects as it considers the entire life cycle of the studied system and it allows looking at different environmental impacts in addition to global warming. However, to assess temporary carbon sequestration and storage projects, it is important to take into account temporal aspects, which current LCA methodology does not allow to do. Indeed, delaying a GHG emission or sequestering a certain amount of carbon and releasing it back to the atmosphere several years later will not have any effect on LCA results as emissions are aggregated in the inventory without any consideration for their timing.
Levasseur et al. have developed a dynamic LCA approach which includes the temporal distribution of the emissions in the inventory, and then uses dynamic characterization factors to determine the time-dependant impact of every emission according to the moment they occur. Dynamic characterization factors have been developed for the global warming impact category by integrating over the time the Absolute global warming potential (AGWP) defined by the Intergovernmental Panel on Climate Change (IPCC) for each GHG [2]. In this paper, the dynamic LCA approach is applied to a 70-year life afforestation project meant to compensate for the impact of an initial 1,000 kg CO2-eq pulse-emission, and evaluates whether the benefits of this temporary carbon sequestration and storage project indeed mitigates the impact of the initial emission. This mitigation is evaluated for several sequestration scenarios.
Dynamic LCA is a flexible approach to consistently consider the timing of the emissions while assessing the impact on global warming of any type of product system. Therefore, it allows evaluating whether a temporary carbon sequestration and storage project compensates for a given GHG emission. Dynamic LCA also allows decision makers to test the sensitivity of the results to the choice of a time horizon for the analysis.

**LC03-3**

**Methods addressing water use in LCA: review and recommendations**

A Kounina[1], M Margni[2], A Köhler[3], E Aoustin[4], S Humbert[1]
[1]Quantis, LAUSANNE, Switzerland
[2]CIRAIG, Ecole Polytechnique de Montreal, MONTRÉAL, Canada
[3]ETH, ZURICH, Switzerland
[4]Veolia, PARIS, France

Stress on global water resources is recognized as an important issue. Although the impacts related to water use on human life, and on biotic and abiotic environments can be considerable, such impacts have only recently been assessed in LCA.
The present project aims at reviewing and performing a systematic qualitative analysis of existing methods linked to assessment of water use. This project is part of the work undertaken by the « Water Use in LCA » working group of the UNEP-SETAC Life Cycle Initiative. The methods are assessed according to a set of pre-defined criteria (completeness of scope; environmental relevance; scientific robustness and certainty; documentation, transparency and reproducibility; applicability and potential stakeholder acceptance) and a procedure as proposed by the ILCD Handbook.This work looks at similarities and differences between methods, identifies key elements and provides indications for deriving operational characterization methods and factors to assess water use in LCA. Interim recommendations on water use modeling, inventory database development and impact assessment methods are formulated to support practitioners in their short term application. The methods evaluation as well as the outcoming recommendations will be presented as the results of this work.
The methods assessed are: Inventory databases: ecoinvent; GaBi; Quantis (in development), WFN database (in development) Inventory methods: WBCSD 2007 (Global Water Tool); Chapagain and Hoekstra 2009; Vince 2007; Boulay 2010; Bayart 2008; Milà I Canals 2009; Peters 2010; Quantis 2010 (in development). Midpoint impact assessment: WFN 2009; Ridoutt and Pfister 2010; Frischknecht 2006; Pfister 2009; Milà I Canals 2009; Boulay 2010;Veolia 2010, Bayart 2008. Damage impact assessment: Pfister 2009; Motoshita 2010; Boulay 2010; Maendly and Humbert 2010; Verones 2010; van Zelm 2010; Bösch 2007 (CExD).

**LC03-4**

**Enhanced structure path analysis: a new method to create spatiotemporally defined Life Cycle Inventory**

D Beloin-Saint-Pierre, I Blanc
Mines ParisTech, SOPHIA ANTIPOLIS, France

Refinements to the Life Cycle Assessment (LCA) methodology are required to obtain realistic and scientifically sound LCA results. We propose to contribute to this goal with the creation of spatiotemporally defined Life Cycle Inventory (LCI).
A fully spatiotemporally defined LCI will ultimately enable its comparison with extractions/emissions (identified as Pressures in the DPSIR framework) from direct environmental analysis models. It then might be possible to validate the same LCI through a comparison with real world observations of substances concentration in the environment.
A method has already been proposed to create LCA results which can be used with spatially resolved impact analysis factors. This method use the same calculation structure as the standard LCA calculation but will encounter difficulties to create temporally resolved LCI.
We propose a new method based on the Structure Path Analysis (SPA) methodology. Here we are mostly interested in the SPA method capacity to identify the linkage between technological processes in a supply chain. This characteristic should enable the use of temporal functions to describe the moments of emissions/extractions for any process of the supply chain. We will present how we define the limits of this calculation and the database requirements for using temporal functions.
The method can work with different level of precision on the spatial and temporal information. This means that LCI results could be assessed by different spatially resolved impact analysis method. The only requirement for this step is to create a translator for varying spatiotemporal information.
This new method called ESPA is a first step to create LCA results which should be more realistic and which might be compared in the future to real world observations first at Pressure level and then at State level by using appropriate models.

**LC03-5**

**Re-engineering LCA for simplicity and flexibility**

BP Weidema
The ecoinvent Centre, DÜBENDORF, Switzerland

With the recent availability of the ecoSpold 2 data format it has become possible to realise the full potential of the design stratgey for database flexibility proposed by Weidema (2003). This design strategy has now been applied to the ecoinvent database, resulting in an LCI database with comprehensive coverage and full flexibility for different applications, for example attributional models with any desired allocation key, and consequential models with any desired level of constraints. At the same time, this design flexibility leads to a reduction in the efforts needed for the maintenance of the database, since allowing many different models to be constructed from the same basic unlinked unit process datasets means that only one dataset needs to be maintained for each unit process, and the maintenance of each dataset can be made independent from the maintenace of all other datasets. Flexibility and simplicity are therefore not contradictions but rather simultaneous results of the new design strategy. The philosophy behind the strategy is explained and several details of the technical implementation are described.

## LC04 - Life Cycle Inventory modelling and attributional/consequential issues (LCI)

**LC04-1**

**Consequential LCA, attributional LCA and scenarios**

R Heijungs
Leiden University, LEIDEN, The Netherlands

Consequential LCA (CLCA) has become a popular mode of LCA modeling. Starting from the

beginning of this century it has significantly grown in number of case study applications. The search term "consequential"yields for the the International Journal of Life Cycle Assessment 77 hits. Now, at SETAC Europe 2011, there is a separate theme "Life Cycle Inventory modelling and attributional/consequential issues (LCI)". This paper discusses the role of scenarios in relation to LCA, consequential or attributional. In doing so, we will focus on the LCI phase.
CLCA builds up a consequential product system from product bottom-up. Consequences all over the world in terms of displaced land, water, energy production, etc. are all modeled from a single product's perspective. Upscaling the results of bottom-up CLCAs independently is very likely to give inconsistent and impossible results. We therefore argue that such bottom-up scenarios may not be the best way to quantify direct and indirect effects for product systems related to main sustainability (transition) problems like energy, land use, water and material/resources use, transport systems etc. For these problems, it might be more appropriate to develop top-down scenarios (from global scenarios to single product consequences, e.g., from global energy scenarios to single product's consequences). Research in this area still needs to be developed further. Some first (incomplete) examples of top-down scenario approaches for LCA are provided.

**LC04-2**
**Scope dependent inventory models: a proposal for the choice between attributional and consequential models**
R Frischknecht, M Stucki
ESU-services Ltd., USTER, Switzerland
Three basically different models exist in life cycle inventory analysis: the attributional, the consequential and the decisional model. We propose criteria that help to classify typical LCA questions regarding real business cases and find the most appropriate LCI model. The framework is applied to a case study of an LCA where attributional and decisional LCI datasets of European electricity mixes are described in order to show the differences of the environmental impacts depending on the modelling approach selected.
Individual decision with comparatively small consequences can be modelled under ceteris paribus (other things being equal) conditions. Decision situations with medium to large potential consequences should be modelled under the conditions of mutatis mutandis (the necessary changes being made). The key question is how to distinguish between small, medium and large consequences. We recommend using the relative economic size to classify objects of investigation and the LCA goals related to them into three groups to which the most appropriate LCI models are assigned.
The attributional approach is sensible for environmental reporting and product labelling and declaration where the relative economic size of the object of investigation is small. The decisional approach is sensible for LCAs of product and process development, as well as site and supplier evaluation carried out by private companies in case the relative economic size of the object of investigation is medium. The consequential approach is of relevance for policy support of governments and international organisations as well as for strategic decisions of companies, where the relative economic size of the object of investigation is large. The European attributional and decisional electricity supply mix causes greenhouse gas emissions of 554 g $CO_2$-eq./kWh and 473 g $CO_2$-eq./kWh, respectively.
The criterion "relative economic size"helps to better decide on the appropriate LCI model to be applied in decisional LCA case studies. The delimitation values proposed (<0.1 %, between 0.1 % and 1 %, >1 %, respectively) are still preliminary and show a certain degree of ambiguity. Nevertheless, the criterion proves to be both practical and potentially relevant. The case study of the European electricity mixes shows that a distinction of different decision contexts is required and feasible. It is recommended to apply the "relative economic size"criterion in the goal and scope phase of any LCA.

**LC04-3**
**Operational LCA guidance for fuel cells: methodological challenges**
P Masoni[1], A Zamagni[1], A Moreno[1], S Ulgiati[2], S Bargigli[2], M Faltenbacher[3], O Shuller[3]
[1]ENEA, BOLOGNA, Italy
[2]Parthenope University, NAPLES, Italy
[3]PE International, STUTTGART, Germany
The main critics addressed to LCA are the lack of robustness, which affects the comparability among different studies on the same product, and the complexity of the method, which hampers its applicability in the industrial context. The subjectivity linked to some methodological choices (e.g. allocation, system boundary definition, modelling, etc.), together with a general inhomogeneity of LCI databases are the main critical aspects. They require a deep knowledge of the technical system analysed as well as of the LCA method, and cannot be referred to the company itself. There is large agreement, not only in the LCA community, that companies need tailor-made provisions, rules and data, which support a life cycle analysis in the sector of interest. In order to meet this urgent need, the JRC-IES has recently published the International Reference Life Cycle Data System (ILCD) Handbook that offers a step-by-step guidance for LCA practitioner. However, the Handbook is applicable to a wide range of different decision-contexts and sectors and therefore needs to be translated to product-specific criteria, guidelines and simplified tools to foster LCA applications in the industry sectors.
This paper presents the first example of a sector-specific operational guidance document on the product group: on "Hydrogen and Fuel cells"(FCs), highlighting the fuel cell part. The Fuel Cells and Hydrogen Joint Undertaking (FCH JU) of the European Commission funds this work, as part of the project FC HyGuide. The approach, "translating"the general ILCD-Handbook into a tailor-made specific guidance document is introduced, showing main methodological aspects choices that have to be addressed.

**LC04-4**
**Electricity trade analysis and marginal technologies in consequential LCA: the case of Quebec's Hydropower in the Northeastern American Market (2006-2008)**
MB Amor[1], PO Pineau[2], C Gaudreault[3], R Samson[1]
[1]CIRAIG-École Polytechnique de Montreal, MONTREAL (QC), Canada
[2]CIRAG-HEC, MONTREAL (QC), Canada
[3]National Council for Air and Stream Improvement, MONTREAL (QC), Canada
Establishing valuable data on marginal energy production technologies is of vital importance in consequential LCA (C-LCA). In electricity production studies, coal or natural gas are often assumed to be the marginal technologies because of generally not publically available specific information due to its strategic value. Moreover, marginal technologies are not static and change as a function of time due to electricity market price and fuel market price volatilities. In the absence of full dispatch information, a procedure to estimate the marginal energy production technologies as a function of time is crucial for more accurate C-LCA results.
The objective of this study is to illustrate the usefulness of the electricity trade analysis in identifying a complex set of hourly**1** marginal technologies and providing reliable data to future C-LCA studies. To achieve this objective, this study focuses on the province of Quebec (Canada), which exports hydropower to its Northeast American neighbors (New Brunswick, New England, New York and Ontario). Over the period 2006-2008, Quebec hourly exchanges of electricity with its adjacent jurisdictions are examined as they increase or decrease their local productions. Moreover, hourly marginal electricity production technologies are identified and validated using the Ontario hourly output per power plant and information released in the Quebec adjacent system operator reports.
Results show that marginal electricity production is characterized by a complex set of technologies able to meet the demand hour-by-hour and not solely by one typical marginal technology (i.e. coal or natural gas). Also, according to our approach, the percentage of hours when hydropower, coal, natural gas or oil are designated as the marginal technology differs on a yearly and jurisdiction basis. These results are crucial to methodological discussion on the identification of the marginal electricity production technology, as it is the case for C-LCA in connection to electricity.
In conclusion, the use of electricity trade analysis as part of the consequential LCA methodology is a cornerstone for establishing, on a yearly average basis, valuable data on the marginal electricity production, as it is the case for Quebec adjacent markets.
**1.** Even if in some cases, such as Ontario, five-minute data would be available, the time unit used was the hour because it is the minimum length at which all data are available.

**LC04-5**
**European energy policies analysis with general equilibrium model GTAP in a consequential and prospective life cycle assessment framework**
T Dandres[1], G Caroline[2], P Tirado Seco[1], R Samson[1]
[1]CIRAIG, MONTREAL (QC), Canada
[2]National Council for Air & Stream Improvement, MONTREAL (QC), Canada
Consequential life cycle assessment (C-LCA) has been developed to study environmental consequences caused by changes occurring in life cycles. Most of the C-LCA have been conducted on small systems affected by marginal variations. Basic economic models and elasticity of offer and demand have been used to assess expected consequences of life cycle marginal changes on economic markets. In this study, C-LCA approach has been applied to a large system of life cycles facing significant variations over 2 decades: economic consequences on world markets of a bioenergy policy applied inside the European Union (EU) between 2005 and 2025 have been modeled with general equilibrium economic model GTAP. Environmental impacts of EU bioenergy policy have been compared to a situation where an EU business as usual energy policy was applied (base situation). Potential environmental impacts attributed to the variation of production caused by EU bioenergy policy on each economic sector in all regions of the word (indirect impacts) and potential environmental impacts attributed to EU energy production (direct impacts) have been calculated. Direct and indirect environmental impacts have been expressed for each 5 years period, per region and per economic sector. Results show that, at world scale, over the whole period, EU bioenergy policy and its indirect consequences would cause fewer impacts on human health, resources and climate change than the base situation but damages on ecosystems would be more important. As expected, coal and wood sectors are significantly affected by EU bioenergy policy. Indeed, EU bioenergy is mostly produced from wood biomass and used to substitute coal in electricity generation. During 2005-2010, benefits of the EU bioenergy policy for human health, resources and climate change are balanced by rebound effects, especially in coal extraction sector. Sensitivity analysis shows that macroeconomic parameters (gross domestic product, population, capital, labor force) and technology innovation used as inputs in the GTAP simulations are quite sensitive parameters that affect the results of the study. This highlight the necessity to develop methods to manage uncertainty related to the use of prospective data and economic model.

## LC05 - Life Cycle Management approaches for different industrial sectors (LCM)

**LC05A-1**
**Life cycle management capability framework: a new approach for sustainable value chains**
W Vigon[1], TE Swarr[2], JA Fava[2], S Valdivia[3], AA Jensen[4]
[1]Society of Environmental Toxicology and Chemistry, PENSACOLA, United States of America
[2]Five Winds International, WEST CHESTER, United States of America
[3]United Nations Environment Programme, PARIS, France
[4]Nordic Inst. for Product Sustainability, Environmental Chemistry and Toxicology, FREDERIKSBERG, Denmark
There is a broad consensus that large multinational corporations (MNCs) should assume responsibility for and manage the social and environmental impacts of their products and services, including the activities of their suppliers. There is also a broad consensus that the best way to hold corporations accountable is to require public reporting of quantitative measures of sustainability performance. Unfortunately, there is less agreement on what exactly constitutes sustainable business performance. Diverse stakeholder interests have resulted in a laundry list of performance measures, recommended practices, and desired outcomes. Capability maturity models have a long history in process quality improvement initiatives. The models provide a structured sequence of activities for improvement. The life cycle management (LCM) capability framework uses a focus on decision- making to provide a simple and practical basis for assessing organizational maturity. The goal is to make decisions with a full awareness of the future and remote consequences of a choice on stakeholders and the natural environment. There were several key lessons learned from Phase 1 which will be discussed in the presentation.

**LC05A-2**
**Rethinking water policy in water-scarce countries: lessons learned from a life-cycle water**

**footprint perspective**

M Martinez Aldaya, S Valdivia, G Sonnemann
UNEP, PARIS, France

As water resources are unevenly distributed and, in some regions scarcity and droughts are increasing both in frequency and intensity, concerns about them are also becoming more and more important on the political agenda. In this context, the United Nations Environment Programme (UNEP) as part of the UNEP's umbrella project entitled 'Water Footprint, Neutrality and Efficiency' (WaFNE) is addressing the growing need to further enhance water efficiency and to improve water quality more holistically, by applying harmonized concepts in water-intensive industries and water-stressed areas especially in the developing world. The final objective is to improve water governance through the engagement of the public and private sectors (business and industry, including financial services) in collaborative work with UNEP. In the same line, developments and discussions on the water footprint indicator are being held under different forums, such as the UNEP/SETAC framework for life cycle impact assessment, the Water Footprint Network and the ISO 14046 Water Footprint Initiative Subcommittee.

Traditionally, governments responsible for water resources management have targeted their policies towards direct water users (such as farmers, industries and households). Recently, however, it has been shown that this approach is limited. Indirect water users and managers, such as final consumers, retailers, traders and all sorts of businesses active along the supply chains of final consumer goods remain out of the scope of governmental policies aimed at mitigating water scarcity and pollution. All water use in the world, however, is ultimately linked to final consumption by consumers. It is therefore interesting to analyze these new multi-sectorial policy aspects and multi-actor approach that have the potential contribute to a better management of water resources.

**LC05A-3**

**Life Cycle Assessment as a decision support tool in the waste management sector: a critical review**

M Niero, A Mazzi, G Simion, A Scipioni
University of Padova, PADOVA, Italy

The purpose of the paper is to present the most recent studies, published in the leading scientific journals, concerning with the application of the Life Cycle Assessment methodology in the solid waste management sector.

First of all, there is an introduction of the current trends of the life cycle analysis in this field, coming from a detailed survey on the LCA studies published in the last five years in the main scientific journals dealing with LCA methodologies and waste management.

The methodology is to identify and describe, for each article, the aim and purpose, the chosen approach, the data and models used, the results obtained and finally the conclusions. For a greater clarity the literature review is made by dividing the LCA studies into different areas: studies of the solid waste management in a broader sense, studies on thermal treatment of waste, studies of specific fractions of waste and studies related to specific processes.

After a presentation of the main common characteristics of every category of articles, a summary is given in order to highlight some common suggestions in the conduction of a life cycle assessment study, coming from this analysis, according to the different aspects: typology of the study (namely if it is a single process-oriented analysis rather than at strategic level), methodology (avoided impacts approach, hypothesis and assumption, data) and results (including the main remarks coming from the life cycle assessment).

As a result the literature review shows that conducting a LCA study in the waste management sector is a still time demanding and complex task, because of the complexity of the systems and the different aspect that have to be taken into account. To conclude some remarks are given on how to perform an LCA study in this sector, with regard to the system boundaries (need to include as much operations as possible, namely, collection, transport, typology of garbage bins), data (prefer site-specific data, including a waste analysis in different times during a year in order to define a medium composition), functional unit (which should be accurately defined in accordance with the scope of the study, considering the possible future variations), hypothesis (which should be accurate with special regard to the National energetic mix, the quality of the waste) and finally methodology (optional step in LCIA phase, sensitivity analysis, including economical considerations).

**LC05A-5**

**LCA software in the analysis of municipal waste treatment technologies**

I Kosinska[1], A Henclik[2]
[1]Warsaw University of Technology, WARSAW, Poland
[2]Mineral and Energy Economy Research Institute of Polish Academy of Science, CRACOW, Poland

Due to the multidisciplinary character of the LCA it has already been successfully applied in different areas of our life. The significant number of publications shows that LCA is a well-known and accepted method used also for the purposes of municipal solid waste (MSW) management. Within the last years there has been a number of LCA software e.g. EASEWASTE, ORWARE developed to calculate potential emissions within the waste management systems or chosen waste management technologies and to define the environmental impacts of the analysed systems or objects.

The study did not intend to compare MSW management scenarios but only specific landfill and incineration technologies. The analysis was performed within the defined system boundaries and based on the chosen functional unit and with a use of three LCA software: GaBi, SimaPro and EASEWASTE.

The aims of the work were to perform: 1) an analysis of chosen incineration plants and a landfill site, 2) a comparison between the analyzed objects (MSW management technologies), 3) a comparison of different software used for calculation of the environmental impacts of MSW technologies.

The results show that landfilling of MSW has a higher potential environmental impact than incineration. Additionally, the calculations that base on the same system boundaries and input data but obtained with alternative LCA software give different values, but keep the same evaluation of analysed objects.

**LC05A-6**

**A comparison among different Automotive Shredder Residue treatment processes**

L Ciacci, L Morselli, F Passarini, A Santini, I Vassura
Bologna University, BOLOGNA, Italy

About 10 million tonnes of waste are generated in Europe from ELVs management chain every year. Currently, 80% of the ELV total weight is recycled during the end-of-life treatment phases, namely: pre-treatment, dismantling, and shredding phase. The remaining 20% is called Automotive Shredder Residue (ASR) and at present it is disposed by landfilling in most European Countries. The complexity of ASR composition, due both spatial and temporal variations, as well as the different source materials shredded (i.e. vehicles and white goods) puts several limits over material recycling processes. ASR valorisation treatments are necessary according to the limit of 13 MJ/kg stated for waste disposal by the Directive 1999/31/EC. Furthermore, the Directive 2000/53/EC claims for ELVs target by the year 2015 (85% recycling rate and 95% recovery rate). The reduction of the current percentage by recovering materials and energy is thus a major challenge for European Community.

In this study a comparison among five ASR management strategies is carried out with a characterisation and a quantification of environmental impacts related to each scenario investigated by means of a Life Cycle Assessment (LCA) approach. These scenarios (landfilling, landfilling after nonferrous metals removal, incinerating, mechanical recycling and gasification) have been compared according to the functional unit of 1 tonn ASR. According to transparency requirements for the sources of data in LCA studies, limits and assumptions of the study are declare. Furthermore, the "Data quality pedigree matrix"was adopted herein in order to declare the quality of data collected. Ecoindicator'99 method has been adopted to assess the main impacts on climate change, carcinogens, respiratory diseases from organic and inorganic substances, acidification/eutrophication effects, ecotoxicity, land use, mineral and fossil fuels depletions.

The results show that industrial processes aimed at matter recovery are the options that can obtain greater environmental benefits compared to present practises. A sensitivity analysis by Monte Carlo approach have been applied in order to evaluate on statistical basis the result. Further improvements will be achieved only by integrating end-of-life treatments into eco-design strategies aiming at a more efficient separation of high value-added materials such as plastics and metals, and leading to a reduction of waste outputs from ELVs management chain.

**LC05B-1**

**Seven barriers to reliable life-cycle assessments for biofuels**

TE Mckone, A Horvath, WW Nazaroff
University of California, BERKELEY CA, United States of America

To address energy security and climate-change concerns, substitutes are needed for petroleum-based transportation fuels. In seeking transportation fuel alternatives to petroleum, policy makers need information to support timely and effective decision-making. In their efforts to provide this information in a reliable and timely manner, life-cycle assessors face a number of barriers. Here we identify and discuss seven barriers that must be addressed in applying LCA to effectively assess the relative sustainability of biofuels as liquid transportation fuels. These barriers include (1) understanding farmers, feedstock options, and land use; (2) mapping out biofuel production technologies and practices; (3) characterizing use-phase emissions and their health consequences; (4) addressing spatial heterogeneity; (5) accounting for time in allocating impacts; (6) assessing transition paths as well as end states; and (7) confronting uncertainty and variability. Recognizing LCA as a process and not a product is key to meeting these challenges. Barriers to LCA arise because many stakeholders expect LCA to provide a clear and final answer"the "truth". This serves only to highlight the flaws and uncertainties of LCA and fails to take advantage of the true power of LCA as an ongoing process that organizes both information and the process of prioritizing information needs. Addressing the world's need for near-term, cost-effective, and reliable production systems for biofuels requires that the technological, social, economic, and environmental challenges be addressed in parallel.

**Design for environment conceptual implementation plan for tanneries, dairy, meat processing and electroplating sectors in Argentina**

JA Gil Donato[1], R Poveda[2], WJ Rogers[1]
[1]West Texas A&M University, CANYON, United States of America
[2]World Bank, BUENOS AIRES, Argentina

The Design for Environment (DfE) conceptual implementation plan was a World Bank sponsored research project applied to the Argentina Industrial Sustainable Development program. The objective of this program is to provide technical and financial assistance to small and medium enterprises of four different industrial sectors (tanneries, meat processing, dairies, and electroplating) to improve their environmental and competitive market challenges. West Texas A&M University was called upon to provide technical assistance in developing the DfE approach and model to identify sustainable alternatives to typical industrial processes. The DfE approach was proposed to develop detailed re-design recommendations for each of the four industrial sectors. In this effort, twelve DfE evaluations and recommendation reports were completed. New markets, regulation needs, and products were identified. Also, WTAMU developed a loan/grant program based on the assumption that improvements to market-competitiveness would be funded by repayable loans guaranteed by the World Bank through local banks. WTAMU selected a loan/grant approach used by the United States Department of Agriculture Natural Resources Conservation Service (USDA-NRCS) as a model for Argentina.

This project provides the approach, design and implementation of DfE to meet Argentine/World Bank objectives. The effort included development of detailed process flow diagrams, technological evaluation to meet and exceed Argentine regulations, estimates of market-competitiveness versus environmental option costs, an examination of feasibility, a comparison of market-competitiveness to environmental goals, and recommended grant-to-loan allocations. The outcome of the project identified alternatives capable of improving competitiveness and attainment of national and government environmental standards.

**LC05B-4**

**LCA and environmental product declaration of an immunological product (vaccine) for boar taint control in male pigs**

P Moraes[1], J Allison[1], JA Robinson[1], GL Baldo[2], F Boeri[2], P Borla[2]
[1]Pfizer Animal Health, MADISON, United States of America
[2]Life Cycle Engineering, TORINO, Italy

1. Introduction

Agriculture, animal farming and related sectors are facing the environmental sustainability challenge by means of advanced analysis tools such as Life Cycle Assessment (LCA) with the goal of understanding the origin of their environmental burden and to propose solutions for impacts mitigation. In 2009, Pfizer Animal Health (USA), in cooperation with Life Cycle Engineering

(Italy), started to apply the LCA methodology to some innovative products, with a first case-study on ImprovacTM, an immunological product (vaccine) for male pigs that, by providing farmers with an alternative way to avoid the problem of boar taint, also allows them to increase the efficiency of male pig production, which may in turn provide considerable life-cycle environmental benefits.
Physical castration (currently the most common method of controlling boar taint) represents the benchmark system. It produces a negative effect on the growth performance of pigs: compared to entire male pigs (boars), castrated (barrows) are less efficient at converting food into body weight and tend to have lower carcasses quality.
The use of Improvac replaces physical castration and allows male pigs to grow as boars for most of their lives: Pigs on an Improvac program naturally eat less feed, create less waste (manure) and have carcasses with a greater percentage of lean meat than barrows. This provides both environmental and market benefits.
2. Objective
This session aims at presenting the results of the LCA study on the complete ImprovacTM system, including the upstream processes in which semi-products and patented medicine components are realised, the core process where the vaccine is manufactured and the downstream processes where the vaccine is used at animal raising level, following through to the slaughterhouse where the meat is produced.
3. Results
The benefits of the Improvac technology can be identified in a reduced consumption of feed, representing around 20% of Global Warming Potential, and a reduced production of slurry, that accounts for about 40% of the total GWP. The LCA study showed a clear environmental benefit in terms of all the main impact indicators of the Improvac system vs. the baseline scenario (physical castration): the conservatively estimated reduction in carbon footprint is near to 4% on a live weight basis (27 kg C02 equivalent for a typical pig), which corresponds to a reduction of about 6% on a one kg of lean meat basis.

**LC05B-5**

**Evaluation of environmental impacts of Epson Italy company through LCA methodology**

GM Magatti, MC Camatini
POLARIS Research Centre - Milano Bicocca University, MILANO, Italy

The LCA evaluation of environmental impacts of Epson company was focused on two main aspects: transport (private and commercial) and services (consumption in the building and the actions of employees). The evaluation was carried out with a questionnaire for the employees and by analysis of data on consumption (electricity, gas, water) and transport (including air travel). LCA was performed with the software GaBi4, to highlight and quantify the environmental loads and energy and was expressed as amount of CO2 emitted.
A questionnaire to all employees was designed to analyze which potential environmental impacts could have their behaviours and determine actions to improve the system. The questionnaire contained 3 sections: transports for employees (full-time workers in Epson building), transports for sales representatives (company car provided) and behaviours in office (for all workers).
Some data coming from transports analysis for employees were: type of vehicles used (private/public), displacement, pollution class and type of fuel; average distance between home and work, average time in minutes to get to work from home.
The parameters tested for the behaviours in office were: heating and air conditioning system, waste and energy consumption, use of resources.
For LCA evaluation we integrated the data collected by the survey (for transport) and those on consumption provided by the company. The balance of the system was determined by impact evaluation method CML2001. We only report the results related to Global Warming Potential, expressed in Kg CO2 equivalent.
The total amount of CO2 equivalent produced annually by Epson results to be 714.26 tons, which means 5.49 Ton CO2 per employee due to the quantity of time spent in office and the journey between home and work. The value resulted to be in the media. In Italy each year are produced 9.5 tons CO2 eq / year per capita (7.6 tons CO2 net - in Lombardy 9.9 Ton CO2 Eq).
The final assessment was related to the amount of CO2 equivalent and GWP impact category, since these parameters are actually the most significant ones for communication. The questionnaire resulted to be very useful for the perception of employees on environmental policy of the company.
Epson has used these results to make important choices: reduce air travel, promotion on video conference, replacement of conventional bulbs with LEDs.

**LC05B-6**

**Food miles in retailers decision making processes**

F Stoessel, S Hellweg, R Juraske
Swiss Federal Institute of Technology, ZURICH, Switzerland

Several European studies have shown that food production and consumption generates 10 - 30 % of the total environmental impact of consumption. About 25 % of Swiss diet consists of fruit and vegetable intake. Most of these products are sold by retailers that can manage their assortment and supply chains with high environmental leverage. In this study it could be shown that detailed LCA analyses of food products, carried out in collaboration with retailers and implemented into the companies' decision making can substantially reduce the impact of food consumption by optimizing where to source vegetables from and how transport them to the final destination.

## NM01 - Detecting, quantifying and characterizing engineered nanomaterials in the environment and in biological systems

**NM01A-1**

**Nanoparticles in food and biological samples**

RJB Peters, S Weigel, H Bouwmeester
RIKILT, WAGENINGEN, The Netherlands

Nanoparticles in food and biological samples
Ruud Peters, Stefan Weigel and Hans Bouwmeester
RIKILT - Institute of Food Safety, PO Box 230, 6700 AE Wageningen, The Netherlands
E-mail contact: ruudj.peters@wur.nl

A variety of nanomaterials are being used in consumer products, in food packaging materials, in some food supplements and even some food products; e.g.silica, silver, titanium, copper, gold and zinc. As a consequence, direct and indirect consumer exposure to nanoparticles is likely. Detection and characterization of nanoparticles in products, food and biological samples of toxicology tests is an essential part of understanding the potential benefits as well as the potential risks of the application of nanoparticles. Single particle ICPMS was used as a screening tool for nanoparticles in food and biological samples. Chromatographic methods in combination with ICPMS have been developed as a confirmation method and have recently been used to show the presence of nano-sized silica in food and drinking water.
In single particle ICPMS nanoparticles in the sample are introduced into the ICPMS plasma producing a plume of analyte ions resulting in a signal spike in the mass spectrometer. From this the size of the particles, their concentration and their size distribution can be calculated. Using the NIST gold reference materials 8011, 8012 and 8013, the method was tested and its performance characteristics determined. This screening method was used in practice for the determination of gold and silver nanoparticles in food supplements and in simulated digestion experiments. In addition, the method was used to detect silver nanoparticles in the livers of rats exposed to silver nanoparticles through their food. The detection of nanoparticles in the liver indicates the actual uptake of such particles from food.
Hydrodynamic chromatography combined with ICPMS was used as a confirmation method to determine the actual size of inorganic nanoparticles. This method was used to determine silica nanoparticles in food items and drinking water. Silica is added to food items as an anti-caking agent known as E551. While this normally exists of larger than nano-sized particles the material has a nano structure with primary particle sizes in the nano-range. Using HDC-ICPMS the presence of nano-sized silica in several food items could be shown. In addition, tap water and several mineral waters were also shown to contain nano-sized silica.

**NM01A-2**

**Characterization of engineered nanoparticles in consumer products**

C Lorenz[1], N von Goetz[1], K Tiede[2], H Hagendorfer[3], S Tear[4], A Ulrich[3], K Hungerbuhler[1]
[1]ETH Zurich, ZURICH, Switzerland
[2]Food and Environmental Research Agency, SAND HUTTON, YORK, United Kingdom
[3]Empa, Swiss Federal Laboratories for Materials Testing and Research, DUBENDORF, Switzerland
[4]University of York, YORK, United Kingdom

Consumer products with engineered nanoparticles (ENPs) are available on the market today in various industrial sectors. The most common consumer products are cosmetics and personal care products, textiles and household products, usually including zinc oxide (ZnO) and/or titanium dioxide (TiO2) as UV-filters or silver (Ag) as an antimicrobial agent. Because consumer products with ENPs are intended to be applied during everyday life, it is expected that human as well as environmental exposure to ENPs is occuring already today and might increase in the near future. Most methods, such as X-ray diffraction or dynamic light scattering, however, work best for the characterization of ENPs with similar shape and narrow size distribution. In case of ENPs in consumer products or environmental samples, the morphology of particles is not known beforehand and ENPs may show a wide size distribution, any agglomeration status or various shapes. The presence of other chemicals or particles in products is an additional challenge.
We have therefore investigated which analytical methods can be used for the characterization of consumer products. TiO2 and ZnO ENPs in sunscreens were investigated with the conventional methods transmission and scanning electron microscopy (TEM and SEM, respectively). Further, we used wet SEM (WetSEMTM) as a new technique. This allowed us to directly analyze the ENPs in pure samples in the state they are applied by consumers, thus avoiding drying artefacts. Additionally, four spray products were analyzed. First, the ENPs in the dispersions (before spraying) were analyzed by TEM in combination with EDS. Elemental analysis was carried out by inductively coupled plasma mass spectrometry. Second, the aerosols generated by the spray vessels were analyzed for ENPs with a scanning mobility particle sizer in combination with TEM analysis.
We conclude that analytical methods that are used for the characterization of nanoparticular powders are not necessarily applicable for the characterization of ENPs in complex media such as consumer products. Generally, several analytical methods have to be combined in order to achieve a comprehensive analysis of the respective ENPs. Focus must further be set on the sample preparation in order to ensure that ENPs are analyzed in the state that is considered relevant. Without previous information on the ENP characteristics, analytical methods have to be chosen carefully to ensure a representative sampling and analysis.

**Determinations of manufactured and incidental nanomaterials in highway runoff waters**

M Hassellöv[1], J Tuoriniemi[2], G Cornelis[1], S Gustafsson[3], K Baumann[1]
[1]University of Gothenburg, GOTHENBURG, Sweden
[2]Univesity of Gothenburg, GOTHENBURG, Sweden
[3]Chalmers, GOTHENBURG, Sweden

In the environment there are three main sources of nanomaterials; natural, incidental and manufactured. The relative proportion of these is unknown but believed to vary in space and time. Little is known about the environmental impacts of these classes, and new methods that can selectively determine them are needed. We have focused on highway runoff waters where especially incidental and manufactured nanoparticles should be significant.
There is a challenge to quantitatively analyze and size nanoparticle in such complex samples and even more difficult to selectively discriminate between different classes or types. We have addressed these problems by developing several approaches and methodologies: i) inductively coupled plasma masspectrometry (ICP-MS) capable of detect and semiquantitatively size single nanoparticles, ii) field flow fractionation to size sort nanomaterials only based on hydrodynamic forces, and iii) optimize an Environmental SEM methodology.
Although most of the mass of metals are transported on larger particles >5 µm, there is a significant fraction also carried on incidental nanoparticles for some metals. The concentration and size distribution trends can be related to rain pattern and traffic intensity.
Some manufactured nanomaterials have been identified in the stormwater runoff and on tunnel wall dust, and the significance of these will be discussed.

**NM01A-4**

**The application of field-flow fractionation for the characterization of nanoparticles in complex samples**

F von der Kammer, E Neubauer, L Legros, B Meisterjahn, Th Hofmann
University of Vienna, VIENNA, Austria

The thorough analysis of nanoparticles comprises a sequence of detection, identification, quantification and if possible a detailed characterization. In a complex sample as soil, sediment or sewage sludge, each step of this sequence is currently still a challenge, and, given a suitable sample preparation, Flow- and Sedimentation-Field Flow Fractionation (Flow-FFF, Sed-FFF) are two of the most promising techniques currently developed for these tasks. The objective is to present sample preparation strategies for natural, silver and gold nanoparticles, principles of method development for proper FFF separation of nanoparticles from complex samples and results obtained

from mixtures of ENPs (Ag and Au) and natural particles. We are demonstrating the potentials and limitations of FFF to distinguish engineered from natural particles.
Metal nanoparticles as citrate stabilized gold nanoparticles do not always intensively interact with typical natural nanoparticles which are in stable dispersion. Conventional ICPMS coupled to FFF seems to be suitable for complex samples containing certain ENPs which are composed predominantly out of elements having a low background in the environment. It is possible to create analytical procedures suitable for the parallel FFF fractionation of natural and gold nanoparticles.

**NM01A-5**

**The silver nano washing machine. Nanoparticle release from a consumer product.**

J Farkas[1], H Peter[2], P Christian[3], JA Gallego Urrea[4], M Hassellöv[4], J Tuoriniemi[4], S Gustavsson[5], E Olsson[5], K Hylland[6], KV Thomas[1]

[5]Chalmers University of Technology, GOTHENBURG, Sweden
[6]University of Oslo, OSLO, Norway

Due to their special physical and chemical properties nanoparticles are increasingly manipulated in industry, research and medical applications. Furthermore, the number of nano-enabled consumer products is rising rapidly, and, since some consumer products were previously seen to release nanoparticles, they are a possible source for nanoparticles to the environment. Routine methods for nanoparticle detection or even quantification in environmental samples are still missing, and environmental concentrations have to be estimated from nanoparticle production and use rates. Studies investigating nanoparticle release can therefore add valuable information for future risk assessments. This study characterizes the effluent from a commercially available silver nano washing machine, investigating the released silver concentrations, number and characteristics of the released nanoparticles and the effect of the effluent on a natural bacterial community.
Average released silver concentration were 11 µg L-1, as determined by inductive coupled mass spectrometry (ICP-MS). Ion selective electrode (ISE) measurements and filtration studies suggested the ionic fraction to be marginal. The presence of silver nanoparticles (AgNPs) was confirmed by single particle ICP-MS and an average number of 80 Mio AgNPs mL -1 was measured. The AgNPs size was determined to be 10 nm and <20 nm with transmission electron microscopy (TEM) and single particle ICP-MS, respectively. Nanoparticle tracking analysis (NTA) measured the particles size to be 60 - 100 nm. The washing machine effluent was shown to have a detrimental effect on a natural bacterial community as it clearly reduced the bacterial abundance. If AgNPs producing washing machines will become a common feature of households, the wastewater will contain significant loadings of AgNPs, which might be released into the aquatic environment.

**Characterization of CeO2 and ZnO nanoparticles in the framework of an eco-toxicological study**

C Minelli[1], J Fabrega[2], CR Tyler[2], TS Galloway[2], R Tantra[1]
[1]National Physical Laboratory, TEDDINGTON, United Kingdom
[2]University of Exeter, EXETER, United Kingdom

Due to their unique physical properties, engineered nanoscale materials are increasingly being used to impart enhanced functionality and improved performance to a wide range of products. As a consequence, human and environmental exposure to these materials is also increasing. For this reason, there is an urgent need to establish robust methodologies for characterizing nanomaterials' properties and assessing their interaction with living organisms.
In this work, we characterize the physico-chemical properties of seven ZnO and CeO2 industrially manufactured nanoparticle (NP) samples in the framework of an eco-toxicological study. We developed methodologies for characterizing NP properties including size, size distribution, aggregation, surface charge and surface chemistry. Substantial effort was dedicated to the development of experimental protocols for the study of NP-catalyzed photo-production of harmful reactive oxygen species (ROS). The NPs were characterized in powder form, as well as after dispersion in DI water, seawater and medium employed in in vitro experiments. The effects of exposure to ZnO and CeO2 NPs on the freshwater Daphnia organisms were also assessed.
Particle size as reported from SEM analysis generally was larger than the relative crystallite size measured by XRD, indicating NP polycrystallinity. NPs with larger sizes were associated with smaller surface areas. When dispersed in media, all NP dispersions were unstable, with tendency to aggregate and sediment. All the NP samples catalyzed the photo-production of ROS, with the largest production observed for the particles smaller in size. The type of media surrounding the NPs was found to affect ROS production. One type of ZnO NPs exhibited a rate of superoxide radical photo-production ten times higher than anatase NPs, which were used as reference materials for photo-catalytic studies. Both CeO2 and ZnO NPs were located in Daphnia organisms after exposure. However, while acute exposure (48h) of Daphnia to CeO2 NPs had no effect on mortality at concentrations up to 100 mg/L, exposure to ZnO NPs caused a concentration-dependent increase on mortality with LC50 of 1.55mg/L.
This study aimed at providing a detailed characterization of the phisico-chemical properties of NPs, to set the basis for understanding NP fate in the environment, their modalities of interaction with living organisms and their toxicological effects.

**NM01B-1**

**ZnO nanoparticle dissolution: measurement with AGNES and modeling**

J Galceran, C David, C Rey-Castro, J Puy, E Companys, J Salvador, J Monné
Univ. Lleida, LLEIDA, Spain

The growing concern on the ecotoxicological issues related to engineered nanomaterials requires the adaptation and developing of analytical and physicochemical techniques in order to gain knowledge on the characteristics of the nanoparticles (NPs) and their behaviour in aqueous dispersions. A distinctive feature of the ZnO nanoparticles is that they can dissolve in aqueous solution in a relatively large proportion [1,2]. Moreover, there are conflicting reports on whether the toxicity of ZnO nanoparticles can be traced back to their nanoscopic properties or rather to the simple fact of their relatively high solubility in natural waters producing a large concentration of Zn(II).
The emerging electroanalytical technique AGNES (Absence of Gradients and Nersntian Equilibrium Stripping) was specifically designed for free metal concentration determination [3]. Moreover, the favourable timescale of this technique allows the measurement in situ of the changing Zn(II) resulting from the dissolution of ZnO nanoparticles. The experimental time evolution of the free Zn concentration when ZnO nanoparticles are dispersed in a medium or when the pH of the medium is modified, allows the study of the kinetic process up to the achievement of the thermodynamical equilibrium or a metastable state. A physicochemical model, which combines surface reaction and diffusion of Zn(II) from the NPs, has been developed to account for the observed kinetic behaviour. Conclusions on the time scale and reversibility of the solubilization process, the key role of the aggregation phenomena and the determination of parameters characterizing the dissolution at different pH values will be shown and discussed in the presentation. The impact of primary size, pH and nanoparticle concentration on the dissolution rate will be discussed, as well as possible environmental consequences.

**Influence of serum protein concentrations and particle characteristics on gold nanoparticle uptake in mammalian cells**

TR Garner, WS Baldwin, AM Rao, SJ Klaine
Clemson University, PENDLETON, SC, United States of America

There are currently over 1000 consumer products on the market that contain or utilize nanomaterials. This number is expected to increase exponentially in the near future in the absence of detailed knowledge concerning the interactions of such materials with biological systems. Furthermore, while nanoparticles have been shown to cross cellular membranes, little research has examined the influence of nanoparticle characteristics on membrane transport. The goal of this project was to characterize the influence of particle size, shape, and surface chemistry on the movement of gold nanoparticles across mammalian cell membranes, as well as the influence of serum protein concentrations on this uptake. Preliminary experimentation has examined the uptake of 4 nm, 18 nm, and 50 nm citrate capped gold nano-spheres in A549 carcinomic human alveolar cells at increasing particle concentrations with a constant concentration of serum proteins, as well as at increasing protein concentrations with constant particle concentrations. Cells were plated in 12-well plates at 100,000 cells per well and exposed in fresh media 24 hours after plating. Accumulation was monitored following 2, 6, 12, and 24 hours. Bioaccumulation of nanoparticles at each time point was quantified by inductively coupled plasma-mass spectrometry (ICP-MS), and movement was visualized using dark field microscopy. Results at a constant protein concentration followed typical dose-response relationships as particle uptake increased with an increase in particle exposure concentration. However, when exposed at the same particle concentration, uptake decreased as serum protein concentrations increased, revealing a negative relationship between these factors (R2=0.92). It is believed that this decrease in uptake is a function of the over-saturation of particles with serum proteins in the media, thus causing competition at the receptor site for receptor mediated endocytosis.

**NM01B-3**

**Characterising the behaviour of engineered nanoparticles in sediment-water systems**

P Luo[1], K Tiede[2], J Pinkstone[1], A Boxall[1]
[1]University of York, YORK, United Kingdom
[2]The Food and Environment Research Agency, SAND HUTTON, YORK, United Kingdom

Novel applications of nanotechnology may lead to the release of engineered nanoparticles (ENPs) into the environment resulting in concerns over their potential environmental impact. To determine their potential ecotoxicity, environmental fate and behaviour, it is essential to be able to detect, quantify and characterise ENPs in the environment. However, the characterisation of ENPs in complex matrices is extremely challenging and the analytical approaches need to be able not only to determine the size and size dirstibution of nanoparticles, but also to differenciate between naturally existing nanoparticles in the environment and the target ENPs. The aim of this study was to invesigate the fate of ENPs in sediment-water systems focusing on the identification and application of suitable analytical techniques for ENP characterisation which overcome the difficulties mentioned above. Partitioning studies of 1 µg ml-1 nano Ag and 1.5 µg ml-1 Au in either artificial or natural sediment were conducted. The 24 h equilibrium partitioning percentage as well as the size distribution of partitioned ENPs were measured using nanoparticle tracking analysis, inductively coupled plasma mass spectrometry (ICP-MS) and transmission electron microscopy (TEM).
This newly developped nanosight method is capable of subtracting the naturally occuring particles and hence estabilish the number concentration of the study ENPs over time as well as the size distribution. It was achieved via the pretreatment of the sediment by vacuum filtration before ENP spiking, centrifugation after equilibration and even dilution before video analysis. Natural sediment-water system was also run in order to correct the interferences from re-released natural NPs into the ENPs spiked system. These results confirm that the partition behaviour of each ENP to the different sediment depend on the nature of functional groups, e.g. citrate coated Au which containing "Na+"accounted higher partition percentage (56%) than the mercaptoundecanoic acid coated Au (35%) to the artificial sediment, Toyopearl SP-650M resin, which is a strong cation exchanger. The study also proved that NTA was capable to provide quantitative information of ENPs regarding the size distribution and number concentrations in complex matrices after appreciate sample preparation. ICP-MS analysis and TEM anlysis of sediment samples is underway.

**Stability of nanoparticles in aqueous dispersions: effects of nanoparticle morphology and surface chemistry**

A Grulke, P Wu, BH Wang, N Mandzy, R Yokel
University of Kentucky, LEXINGTON, United States of America

Analyzing the physico-chemical properties of engineered nanomaterials (ENMs) as they are dosed to organisms, released into the environment, or taken up by organisms remains one of the important challenges in conducting meaningful studies of their environmental behavior and toxicology. Released ENMs can enter drinking water, food materials, or organisms. Understanding the stability of ENMs in aqueous dispersions is essential to obtaining reliable environmental impact and toxicological results. This work relates the stability of metal oxide nanoparticles in aqueous dispersions to their morphologies and surface chemistries. Liquid phase compositions include some buffer systems as well as dilute protein solutions. A set of complementary analytical tools (transmission electron microscopy (TEM) with electron energy loss spectroscopy (EELS) and energy-dispersive x-ray (EDS; scanning electron microscopy (SEM); dynamic light scattering (DLS); z- potential; Fourier transform infrared spectroscopy (FTIR); thermogravimetric analysis (TGA); x-ray photoelectron spectroscopy (XPS); and X-ray diffraction (XRD)) were used to evaluate the complex morphologies and surface chemistries that can occur. These ENMs are 'monodisperse' ceria samples with primary particle sizes similar to those now being used to reduce soot and improve efficiency during the combustion of diesel fuels. The ceria samples in this study had primary particles known to be unaggregated. These materials have high purity (XRD and EDS), no internal porosity (BET), and are highly crystalline (TEM), leading to controlled surface chemistries (confirmed by EELS under HRTEM, FTIR, TGA, and XPS). The surfaces of these ENMs can sorb metabolic salts, e.g. the citrate ion, and proteins (such as globular proteins) in aqueous systems. In some cases, buffer salts can cause agglomeration or precipitation of the nanoparticles. Dispersion stability has been evaluated using DLS and z-potential. Surface sorption of metabolites and proteins can occur in 'layers' (confirmed using FTIR and TGA techniques), which leads to changes in the z-potential curves for the nanoparticles. These findings have relevance to understanding the behavior of ENMs in the environment and in organisms (including human health).

**Transformations of silver nanoparticles at environmentally relevant concentrations in fresh and saline surface waters**

EM Heithmar[1], SA Beres[2], EM Siska[3]
[1]US EPA, LAS VEGAS, United States of America
[2]PerkinElmer, WALTHAM, United States of America
[3]Student Contractor to US EPA, LAS VEGAS, United States of America

Predicting the fate of silver engineered nanomaterials (ENMs) in surface waters requires an understanding of how the size distributions of different silver ENMs are affected by water chemistry. Conventional techniques for measuring nanoparticle size distribution, such as electron microscopy or light-scattering methods, are not applicable for measuring size distributions at environmentally relevant silver nanoparticle concentrations in media containing background nanoparticles of other material. Field flow fractionation (FFF) coupled with inductively coupled plasma mass spectrometry (ICPMS) is one approach for such measurements, but FFF-ICPMS is limited to silver concentrations above about 10 µg/L, and it cannot distinguish between silver-containing particles of even greatly differing elemental composition. We apply an alternative approach, called single particle ICPMS (SP-ICPMS), to study the effect of water chemistry and silver nanoparticle concentration on transformations of silver ENMs in synthetic and real surface waters. Silver nanoparticles in NaCl suspensions with similar salinity to open seawater undergo aggregation, in agreement with established theory and previous studies at higher concentration. They also undergo size reduction consistent with dissolution. The dominant process (aggregation or dissolution) depends on particle size and concentration. Size transformations in suspensions of silver nanoparticles in real surface waters are also studied. The efficacy of SP-ICPMS in measuring nanoparticle transformations in these complex media is evaluated as a function of plasma and data acquisition parameters, and optimal conditions are described. Studies of a range of nanoparticle sizes and environmentally relevant concentrations are presented. The effect of natural organic matter on transformation kinetics and equilibria is presented.

**Absorption of functionalized single-walled nanotubes across Daphnia magna gut tract**

J Edgington[1], R Podila[2], A Rao[2], E Peterson[3], SJ Klaine[1]
[1]Clemson University, PENDLETON, United States of America
[2]Clemson University Department of Physics and Astronomy, CLEMSON, United States of America
[3]National Institute of Standards and Technology, GAITHERSBURG, United States of America

Engineered carbon nanostructures, such as single-walled carbon nanotubes (SWNTs), are inherently hydrophobic and are not stable in aqueous systems. However SWNTs can be surface modified with functional groups that will affect aqueous stability. Furthermore, the aqueous stability and bioavailability of these nanotubes may be influenced by the water quality parameters such as ionic strength, pH, and natural organic matter (NOM). NOM may interact with the functionalized surface of SWNTS resulting in increased aqueous stability. This enhanced stability is likely to lead to an increased residence time in the water column and increased exposure times for pelagic organisms. While our previous work demonstrated that multiwalled carbon nanotubes (MWNT) stayed within the gut tract of D. magna, some researchers have suggested that the small diameter of SWNTS may allow them to cross cell membranes. In the present study NOM from Suwannee River (SR-NOM) increased the stability of OH, SiO2, polyethylene glycol (PEG), and polyaminobenzene sulfonic acid (PABS) functionalized SWNT suspensions. Standard 96 hr static renewal D. magna toxicity tests were conducted to evaluate the acute toxicity of these functionalized SWNTs. Particles were characterized using zeta potential, dynamic light scattering, and transmission electron microscopy (TEM). Confocal microscopy, micro Raman spectroscopy, and TEM coupled with electron emission loss spectroscopy (EELS) were also used to inspect the gut tracts of D. magna to determine the fate of ingested functionalized SWNTs. Functionalized SWNT exposure to D. magna caused little acute toxicity compared to published data on MWNT. Confocal microscopy and micro Raman techniques provided evidence that functionalized SWNTs greatly impact the gut tract once ingested, but were unable to work at the scale needed to determine material absorption. TEM coupled with EELS provided the best evidence for material absorption across the gut tract. The data suggest that SWNTs surface modified with more basic functional groups, OH and SiO2, may have more of an ability to absorb across the gut tract than those surface modified with larger PEG and PABS functional groups.

## NM02 - Fate and effects of nanoparticles

**NM02A-1**

**Assessing ionic silver availability to algae from differently coated silver nanoparticles**

E Navarro[1], B Wagner[2], N Odzak[2], L Sigg[2], B Behra[2]
[1]CSIC-Spanish National Research Council, ZARAGOZA, Spain
[2]Eawag, DÜBENDORF, Switzerland

Because its biocide properties, silver nanoparticles (AgNP) are present in numerous consumer products. Toxicity of AgNP to organisms is related with both the formation of ionic silver ($Ag^+$) and interactions between AgNP and $Ag^+$ with cell membranes. At present methodological limitations result in underestimation of readily bioavailable ionic silver, especially if ionic silver is formed at nanoparticles-cell interface and is immediately taken up by cells.
In this work we propose a method to examine the role of $Ag^+$ in explaining toxicity of AgNPs to algae, by using cysteine to assess $Ag^+$ bioavailability. We assessed the toxicity of AgNPs coated with 5 different chemicals (carbonate -CO3-, polyetheleneglycol -PEG-, lactate -LAC-, chitosan -CHI- and polyvinyl pyrrolidone -PVP-) on the photosynthesis of Chlamydomonas reinhardtii. Based on total Ag concentration, AgNP EC50 ranged from 0,78 µM (PVP) to 2,98 µM (CO3). In a subsequent experiment cysteine completely abolished AgNP toxicity, indicating that toxicity was mediated by $Ag^+$ and at the same time that different coatings were not toxic to photosynthesis. Hence, it was expected that EC50 values calculated as a function of the $Ag^+$ present in the experimental suspensions (and assessed using chemical analysis) would converge to similar values. But, these values showed again a wide range of variation, from 0.03 µM Ag+ (CO3) to 0.2 µM Ag+ (PEG).
Then, we considered the possibility that $Ag^+$ concentration used to calculate EC50 was underestimated. We calculated the cysteine concentration required to completely abolish toxicity of AgNPs EC50, as an estimate of bioavailable $Ag^+$ (cysteine binds Ag+ in 1:1 stoichiometry). Results shown that all EC50 AgNP required similar values of cysteine (from 0,405 to 0,500 µM) to completely abolish toxicity to photosynthesis. Hence, Ag+ bioavailable to algae was in all cases around 0,4-0,5 µM. Results indicate a) the formation of $Ag^+$ at the nanoparticles-cell interface, b) cysteine allows estimating $Ag^+$ concentration bioavailable in experiments with algae and c) cysteine also allowed concluding on the potential toxicity of coatings.

**NM02A-2**

**Toxicity of silver nanoparticle to freshwater algae and cyanobacteria**

M Matzke[1], M Halling[1], J Gallego[1], M Hassellöv[2], T Backhaus[1]
[1]University of Gothenburg, GÖTEBORG, Sweden
[2]Department of Chemistry, GOETEBORG, Sweden

Nanoparticles (NPs) display special chemical properties because of their size, shape, composition and electronic structure. These properties lend NPs their functionality, but may also led to toxic effects. Due to their widespread use in consumer products an exposure of the aquatic environment to NPs is anticipated and already proven in first analytical surveys. Especially metal/metaloxide NPs are widely used, of which silver nanoparticles (AgNPs) have gained considerable attention due to their broad microbiocidal properties. This implies a specific hazard for exposed aquatic primary producers (algae). In order to identify the most suitable test species for the hazard assessment of AgNPs, we determined the toxicity of two AgNPs (10 nm nominal size, uncoated and 40nm size, citrate coated) to the green algae Pseudokirchneriella subcapitata and Chlamydomonas reinhardtii, the diatom Cyclotella meninghiana and the cyanobacterium Synechoccocus leopoldensis. To test if the toxicity was particle related or caused by free Ag+ ions only, we tested AgNO3 in the same total silver concentrations. All studies were accompanied by chemical analytics: TEM, ICP-MS (total silver content and Ag+ ions), ultrafiltration/centrifuge-aided membrane filtration (Ag+ ions) and Nanoparticle Tracking analysis (NTA) to determin the particle size distribution (NanoSight system). A difference of approximately one order of magnitude was found for the EC50 values of the two AgNPs for Chlamyodomnas. For all other species the EC50 values for the two AgNPs were similar. The sensitivity of the tested species was clearly different, the EC50 values differed by a factor of 8 for AgNP40 and 14 for AgNP10. The lowest EC50 was always observed for the cyanobacterium Synechococcus. However, different shapes of the concentration-response curves led to a more complex picture for the low-dose range (NOECs). Here the green algae were more sensitive. AgNO3 proved to be most toxic for all species, approximately one order of magnitude more toxic than AgNPs. The ecotoxicological results will be presented and discussed in relation to the analytical data.
Further studies are necessary to identify the causes for the differences in species sensitivity and curve shapes. Hence, within the next couple of months we will investigate the modes of action of the AgNPs and AgNO3, in particular the formation of ROS (reactive oxigen species) and effects on membrane integrity by applying various fluorescence methods.

**NM02A-3**

**Fabrication and ecotoxicological assessment on microalgae of coating magnetite nanoparticles with humics**

AA Yurishcheva[1], KA Kydralieva[1], GI Dzhardimalieva[2], AA Zaripova[3], AD Pomogailo[2], SI Pomogailo[2], ShJ Jorobekova[3], A Karateeva[4], VA Terekhova[4], DN Matorin[4]

[3]Institute of Chemistry & Chem. Technology, BISHKEK, Kyrgyzstan
[4]Moscow State University, MOSCOW, Russian Federation

The research was aimed to fabricate of magnetoactive composite based on coating Fe3O4 nanoparticles with humic substance using mechanochemical technique and to estimate the toxicological potential of nanocomposite fabricated. The nanocomposite obtained were characterized by XRD, Mössbauer, SEM and TEM studies. It has been demonstrated Fe3O4 nanoparticles stabilized by humic substances (Fe3O4/HS) have mean size of the particles - 7-16 nm.
The response of test-organisms, green alga Scenedesmus quadricauda to nanocomposite Fe3O4/HA was investigated in laboratory experiments. The testing of Fe3O4/HA toxicity by measuring fluorescence parameters of microalgae revealed a marked suppression of photosynthetic activity of the algal culture at concentration of aqeous suspension of the composite 0.1%. In samples of algae, grown in nutrient depleted medium (culture water), the lethal concentration was equal to 0.01%, which is by an order of magnitude lower, than that in alga grown in the Uspensky medium.
Analysis of fluorescence characteristics in algae showed a decrease in the quantum yield of photochemical conversion of light energy in photosynthesis and in the relative rate of the noncyclic electron transport in algae under the effect of Fe3O4/HA. The shape of fluorescence induction curve changed in the presence of Fe3O4/HA, which could be seen in the changed ratio of different induction peaks. Fe3O4/HA was found to exert acute toxic effect on Scenedesmus at concentration 0.01%.

[5]Eawag - Swiss Federal Institute of Aquatic Science and Technology, DUEBENDORF, Switzerland

The forecasted augmentation in the manufacture and use of engineered nanomaterials (ENM) makes it likely that increasing human and environmental exposure will occur. Carbon nanotubes (CNT) are one major building block of nanotechnologies and their environmental and health effects are currently under heavy investigation. CNT may have direct ecotoxicological effects on organisms. However, they are also strong adsorbents for many organic compounds and may thus influence their bioavailability. In the natural environment, ENM will always occur together with a great number of organic micropollutants. The fate and the toxic effects of this kind of mixtures

on organisms are today not characterized.
The aim of our study was therefore to systematically quantify the interactions in an aqueous ternary biota-nanoparticle-pollutant laboratory system. Experiments were performed with the green alga *Chlorella vulgaris* as model organism, different multi-walled CNT as nanoparticles and the herbicide diuron as a model pollutant. Effects on *C. vulgaris* were determined as in vivo photosynthetic activity. In parallel, the aqueous diuron concentration was measured with a Varian LC-MSMS system. The binding affinity of pollutants to the CNT, the impact of CNT on the bioavailability of pollutants, and the ecotoxicological effects of CNT on algal photosynthesis were determined.
The results show that the presence of CNT drastically reduced the dissolved diuron exposure of algae. Therefore, the primary effect was that CNT reduced diuron toxicity. For instance, in the presence of 10 mg CNT/L, a nominal concentration of 150 µg/L of diuron caused a 50% inhibition of the photosynthetic activity only. For comparison, the EC50 of diuron without CNT was around 35-90 µg/L and comparable to literature data. However, the toxicity of diuron in the presence of CNT was significantly higher than predicted from the dissolved diuron concentration alone, especially after longer exposure of the algae to the mixture. The comparison of the photosynthetic activity measurements and the LC-MSMS measurements of dissolved diuron shows that the presence of 10 mg CNT/L increased the diuron toxicity by a factor of roughly 3.5 compared to the same diuron concentration without CNT, especially after longer exposure of algae to the mixture. This enhanced toxicity might be explained by a enhanced availability of diuron due to high levels of CNT near the algal surface.

**Sublethal effects of a set of nanoparticles of industrial interest on different experimental systems from protozoa to human cells**
B Burlando, E Ranzato, S Martinotti, S Sforzini, L Oliveri, A Viarengo
DiSAV Department of Environmental and Life Sciences, ALESSANDRIA, Italy
In this research the environmental impact of nanostructured composites have been investigated. We have carried out in vitro toxicological tests in order to evaluate possible noxious effects of nanomaterials selected to develop new nanocomposite products.
We have used HaCaT cells, a line of immortalized keratinocytes representing an in vitro model of human epidermis. Hence, our in vitro model allows to assess potential toxic effects of dermal exposure to nanomaterials. The skin is a preferential route by which nanomaterials come in contact with the human body.
In addition, to evaluate the possible effects at the environmental level, the model organism *D. discoideum* has been utilized. This social ameba has been used to study nanoparticle effects on mortality and reproduction rate, and to analyze sublethal endpoints such as endocytosis rate, lysosomal membrane stability (LMS), and genotoxicity.
In order to highlight the cytotoxic effects of nanomaterials on HaCaT keratinocytes, cells have been incubated for 24h with each material at increasing doses of 0.5, 10 and 100 µg/mL. The comet assay has been performed by using 10 and 100 µg/mL only, due to negligible effects observed with the lowest dose in preliminary tests.
The results have shown that sepiolite is the most toxic compound, since it has induced both apoptosis and necrosis starting from the lowest concentration of 0.5 µg/mL, and moreover is genotoxic starting from 10 µg/mL. Next follows cloisite, which induces apoptosis and necrosis at all concentrations, but is genotoxic only at the highest dose of 100 µg/mL. Two other compounds, OC and POG, have shown a lower toxicity, consisting in a dose-dependent apoptosis and a very limited or null necrosis. However, POG has also induced genotoxic damage close to that observed with sepiolite. BNB90 and DAPS have produced even lower toxic effects, consisting in the nearly complete absence of necrosis and limited apoptosis and DNA damage. Finally, bohemite has shown very limited toxicity, consisting of a slight but significant genotoxic damage at 100 µg/mL, while carbon nanotubes have induced no toxicity at all.
By using *D. discoideum* as a model organism, a similar toxicity ranking among the compounds has been obtained. However, data indicate that the selected endpoints are able to detect negative effects on replication rate and/or LMS at nanoparticle concentrations lower than 1 µg/ml, while DNA damage was evident only at higher concentrations.

**NM02A-6**
**The aquatic toxicity and species sensitivity distributions of metal oxide nanoparticles**
NC Adam, C Schmitt, D Knapen, R Blust
University of Antwerp, ANTWERP, Belgium
The production of metal oxide nanoparticles has recently increased and in the future, nanoparticle-based products will become more and more commercially relevant. This increasing production will inevitably lead to a runoff to the aquatic environment. However, the knowledge of the potential risk and corresponding risk assessment procedures of metal oxide nanoparticles considering aquatic organisms are still limited. Therefore, our research focuses on the toxicity of these types of nanoparticles and more specifically on ZnO and $SiO_2$. Crustaceans (*Artemia franciscana* and *Daphnia magna*), algae (*Pseudokirchneriella subcapitata*) and fish (*Danio rerio*) were exposed in acute toxicity tests to the nanopowder, the nanodispersion as well as the bulk material of $SiO_2$ and ZnO. After 48 to 96 h (depending on the type of species), endpoints were determined (mortality for *A. franciscana* and *D. rerio*, immobilisation for *D. magna* and growth inhibition for *P. subcapitata*). Additionally, a setoff toward chronic toxicity testing has been done for ZnO nanoparticles and bulk material on *Daphnia magna*, with reproduction as a toxic endpoint. Our acute results showed that the exposure to the three different $SiO_2$ forms had no significant impact on any of the observed endpoints for *A. franciscana*, *D. magna* and *D. rerio*. However, the growth of *P. subcapitata* was significantly inhibited when exposed to the $SiO_2$ nanodispersion ($EC_{50}$: 23.1 mg/L), nanopowder ($EC_{50}$: 48.6 mg/L) and bulk material ($EC_{50}$: 28.0 mg/L). Moreover, ZnO nanoparticles and bulk materials appeared to be toxic to *D. magna* ($EC_{50}$ dispersion: 2.40 mg/L, $EC_{50}$ nanopowder: 3.10 mg/L, $EC_{50}$ bulk: 4.22 mg/L) and *P. subcapitata* ($EC_{50}$ nanodispersion: 0.03 mg/L, $EC_{50}$ nanopowder: 0.05 mg/L, $EC_{50}$ bulk: 0.04 mg/L). *A. franciscana* and *D. rerio* were not affected in the acute tests by any of the tested ZnO forms. The results indicate clear differences in species' sensitivities to the different nanoparticles. Therefore, an initiation towards a nanoparticle risk assessment was made by means of the construction of acute species sensitivity distributions. In the future, additional chronic toxicity tests will be performed to gain more insight in nanoparticle toxicity.

**NM02B-1**
**Effects of natural water chemistry on nanosilver behavior and toxicity**
J Mclaughlin, JG Clar, JC Bonzongo
University of Florida, GAINESVILLE, United States of America
The success of nanotechnology will undoubtedly lead to the increased introduction of NPs to natural systems; and aquatic systems which integrate contaminant inputs from atmospheric deposition and terrestrial surface runoffs will likely act as sinks for these new pollutants. Differences in the chemical make up of these aquatic systems will control changes in surface properties of NPs, and could therefore impact their environmental behaviors, fate and interactions with both biotic and abiotic particles. A series of batch experiments were conducted to determine the effect of natural waters with different solution chemistries on nanosilver (nAg) particle dispersion, stability, and toxicity. A combination of physical, biogeochemical, and toxicological methods were used to characterize, track changes, and assess the biological impacts of nAg suspended in natural waters, both raw and manipulated. Briefly, the results show that: (1) nAg suspended in natural waters with high DOC/Ionic strength ratios have average particle sizes < 100 nm and behave as stable suspensions, while natural waters with high ionic strength/DOC ratios have average particle sizes >200 nm, resulting in less stable suspensions (2) the exposure to nAg using Ceriodaphnia dubia and Pseudokirchneriella subcapitata shows highest toxicity in culture media and natural waters with high ionic strength/DOC ratios. Overall our findings do not only help establish needed correlations between nAg particle properties and the potential for environmental exposure, but also the much needed information in support of the development of an overall risk assessment plan for nAg.

**NM02B-2**
**The impact of silver nanowire length and surface coating on physicochemical properties in environmental media and on nanowire toxicity to Daphnia magna and Fathead minnow cells**
C Vulpe[1], A Tagmount[1], L Scanlan[1], C Clark[1], C Tran[1], P Luong[1], D Nowinski[1], D Lam[1], B Gilbert[2]
[1]Univ. of Ca, Berkeley, BERKELEY, United States of America
[2]2Lawrence Berkeley National Laboratory, BERKELEY, United States of America
Nanowires are distinct class of high-aspect-ratio inorganic nanomaterials. AgNW represent a class of metal nanowires likely to have widespread applications in electronic devices. While there is extensive information on the environmental toxicity of many nanoparticles, there is very limited information on the potential toxicity of nanowires to aquatic organisms.
We have begun to address the potential impact of nanowires in the environment by assessing the physicochemical properties in relevant environmental media as well as the toxicity of silver nanowires (AgNW) to *Daphnia magn*a and Fathead minnow (*Pimephales promelas*) cell lines. We found that the solution behavior and toxicity of AgNW are affected by the nanowire dimensions (30 nm x 2 µm vs. 65 nm x 20 µm), surface coating (polyvinyl pyrrolidinone, PVP, vs. silica), solution chemistry in environmental media and interactions with media components. Future applications of nanowires must consider the potential environmental toxicity.

**NM02B-3**
**Effects of environmental factors on the toxicity & bioavailability of silver and gold nanoparticles using a battery of marine species**
AL Macken[1], HJ Byrne[1], k Hylland[2], K Thomas[3]
[1]Focas Research Institute, DUBLIN, Ireland
[2]Biologisk institutt, Universitet i Oslo, OSLO, Norway
[3]NIVA, OSLO, Norway
This project is a collaborative project between the Norwegian Institute of Water Research (NIVA), University of Oslo (UiO) and the Focas Research Institute and is funded by the Research Council of Norway and the Integrated NanoScience Platform of Ireland (INSPIRE).
The aim of the work was to investigate the interaction between nanoparticles (NPs) and marine species under realistic environmental conditions. Their toxicity under varying environmental conditions (e.g. salinity), potential uptake routes and their potential to associate with other marine contaminants (mixture toxicity) were all investigated. The objectives of this collaboration were to (1) investigate the toxicity and uptake of standard nanoparticles, to a battery of marine species, (2) understand and elucidate the effects of varying natural environmental conditions (e.g. salinity) on the toxicity of standard NPs to the previously tested battery of species, (3) include a thorough characterisation of the NPs under realistic environmental conditions for use in the interpretation of behaviour in the marine environment, (4) establish collaborative research links between the Focas Research Institute, NIVA and UiO for future research collaborations and exchange of expertise.
Two marine species, the harpacticoid copepod *Tisbe battagliai* and the Rhodophyte *Ceramium tenuicorne* were selected for testing as they represented different trophic levels and ecological niches.
To investigate the effects of salinity and to compare the sensitivity between species, Ag-PVP NPs were assayed at a range of salinities with the two test species. The *T. battagliai* assays were carried out in natural seawater of ca. 35"ð, while *C. tenuicorne* was assayed in 2A media at three different salinities 10, 20 and 30"ð. To ensure the performance of the test species, reference toxicants were run in parallel. Further assays with AgNO3 were carried out under all conditions to account for toxicity due to ionic silver and compared with the NP assays. All results are discussed in the context of sensitivity and varying salinities.
The uptake of Ag-PVP was also investigated in both species using TEM techniques. The potential for NPs to modify the toxicity of some common contaminants to *T. battagliai* is also discussed in relation to gold NPs. A thorough characterisation of all NPs in all media was conducted to support the toxicological findings.

**NM02B-4**
**Effects of different n-oxides of similar size on bivalve immunocytes**
L Canesi[1], D Bilanicova[2], B Canonico[3], G Gallo[1], A Marcomini[2], G Pojana[2], C Ciacci[3]
[1]University of Genoa, GENOA, Italy
[2]Dip. di Scienze Ambientali, Università di Venezia, VENEZIA, Italy
[3]DISUAN, Università di Urbino, URBINO, Italy
The aquatic environment represents the ultimate sink for manufactured nanomaterials and nanoparticles (NPs). Bivalve mollusks can represent a relevant group of test organisms for investigating the aquatic ecotoxicity of NPs. In bivalves circulating hemocytes, resembling the monocyte/macrophage lineage, are responsible for cell-mediated immunity. In Mytilus galloprovincialis, hemocytes have been shown to represent a sensitive target for the effects of various engineered NPs. The observed immunotoxic/inflammatory effects were mediated by activation of kinase-mediated cell signaling.
Data are presented on the in vitro effects and mechanisms of action of different n-oxides of the same nominal size (20-30 nm) (nTiO2, n-SiO2, n-ZnO, n-CeO2) on mussel hemocytes. Physico-chemical characterization of NPs was performed before experiments by various tecniques such as Scanning Electron Microscopy (SEM), Transmission Electron Microscopy (TEM), gas physical adsorption (BET), Dynamic Light Scattering (DLS), Inductively Coupled Plasma (ICP), etc.. DLS analysis revealed the formation of nano- and micro-sized agglomerates of NP suspensions in artificial sea water (ASW). Hemocytes were exposed to NPs (1, 5 and 10 _g/ml)

for different times (from 30 min to 4 hr) and functional parameters were evaluated: lysosomal membrane stability (LMS), ROS and NO production, lysozyme release. Moreover, cytosolic pH and apoptotic changes were measured by Flow Cytometry.
The effects on hemocyte LMS were dose dependent, with ZnO>TiO2@SiO2>CeO2 and unrelated to their actual size distributions. Differential effects were also observed, depending on the type and concentration of NP, with n-SiO2 showing the strongest effects on ROS and NO production, n-TiO2 inducing dose dependent lysozyme release, ZnO resulting in cytotoxic effects. The role of stress-activated MAPKs in mediating the responses were investigated. The results are discussed in relation to NP chemical composition and behaviour in ASW and mechanisms of action.
Overall, the utilization of immunotoxicity tests in mussel hemocytes represents an useful model that could provide rapid information when screening the potential impact of different NPs on aquatic organisms.

**NM02B-5**
**Ecotoxicology of gold nanoparticles in endobenthic invertebrates, the tellinid clam Scrobicularia plana and the polychaete worm Nereis diversicolor**
JF Pan[1], PE Buffet[2], L Poirier[2], C Amiard-Triquet[2], D Gilland[3], M Guibbolini[4], C Risso[4], M Roméo[4], E Valsami-Jones[5], C Mouneyrac[1]

[2]University of Nantes, NANTES, France
[3]European Commission, ISPRA, Italy
[4]University of Nice-Sophia Antipolis, NICE, France
[5]Natural History Museum, LONDON, United Kingdom
Despite gold nanoparticles'expansive utilization and promising future in various fields, only a few studies deal with their behaviors or impacts on aquatic organisms in coastal environments. We explored the biochemical (biomarkers) and behavioral (burrowing kinetics and feeding rates) responses of two estuarine invertebrates Scrobicularia plana and Nereis diversicolor to gold nanoparticles (Au NPs) of three sizes (5, 15 and 40 nm) during a 16 d laboratory exposure at 100 µg L-1. In seawater the aggregation of Au NPs leads to a distribution with a maximum peak at 0.6 µm. After exposure, the Au body concentrations ranged from 6.0 to 29.2 µg g-1 wet wt for clams, and from 0.4 to 5.3 µg g-1 wet wt for ragworms. The bioaccumulation was higher for both clams and ragworms exposed to bigger NPs. Concerning results of defence (Metallothionein-like proteins: MTLPs, catalase: CAT, glutathione-S-transferase: GST and superoxide dismutase: SOD) and damage (thiobarbituric acid reactive substances: TBARS and acetylcholinesterase activity: AChE) biomarkers, Au NPs induced MTLPs in clams. Au NPs of 40 nm exposure also increased the activities of CAT (19%), GST (86%) and SOD (41%) in clams and those of 5 and 15 nm also increased GST activities by 60% and 82%, respectively. The Au NPs did not influence the lactate dehydrogenase (LDH) activities in clams, indicating no change of animal metabolic condition. In contrast, in ragworms, the Au NPs exhibited negligible alterations of CAT (except in 40 nm, increased by 46%), GST and SOD activities; however, a significant elevated LDH activity (41 -52%) was observed compared to control. For clams, no significant oxidative damage was observed referring to the comparable TBARS levels after exposure to all the three size Au NPs; while ragworms demonstrated 33 - 42% decrease in TBARS activities compared to control. Both species revealed no neurotoxicity effects following Au NP exposure compared to controls but in contrast increased AChE activities. These results could be explained by a stabilization effect of AChE by Au NPs leading to a minimal loss of enzyme function. Following the exposure to Au NPs, the burrowing kinetics were notably impaired for both clams and ragworms. Moreover, feeding rate also decreased markedly for ragworms. Because different species exhibit various mechanisms for fighting the nanotoxicity caused by nanomaterials, it is advised to use several aquatic organisms as biomornitoring models in aquatic environment.

**NM02B-6**
**Effects of ionic-Cu, nano- and micro- CuO particles in the deposit-feeding snail, Potamopyrgus antipodarum**
C Pang[1], H Selck[1], S Misra[2], D Berhanu[2], A Dybowska[2], E Valsami-Jones[2], V Forbes[1]
[1]Department of Environmental, Social and Spatial Change, Roskilde University, ROSKILDE, Denmark
[2]Natural History Museum, LONDON, United Kingdom
Increasing use of nanoparticles (NPs) is likely to result in release of these particles to the aquatic environment where the NPs may eventually accumulate in the sediment compartment. However, little is known about the potential ecotoxicity of engineered NPs. We here consider the case of metal oxide NPs using CuO to understand if the effects of NPs deviate from micron-sized particles of CuO and ionic-Cu. To address this issue, we compared effects of sediment-associated ionic-Cu, nano- and micro- CuO particles to the deposit-feeding snail, Potamopyrgus antipodarum. Effects were assessed as mortality, specific growth rate, feeding rate, reproduction, and bioaccumulation after 8 weeks of exposure to nominal concentrations 0, 30, 60, 120 and 240 µg Cu/g dry weight sediment. Copper was administered in three forms: ionic Cu, 7nm CuO, and 5 µm CuO. The results demonstrate that nano-CuO had greater effects on growth, feeding rate, and reproduction of P. antipodarum than micro-CuO or ionic Cu. P. antipodarum accumulated more nano-CuO than ionic-Cu or micro-CuO, suggesting that consideration of metal form may be important when assessing risks of metals to the aquatic environment.

**NM02C-1**
**Toxic effects and bioaccumulation of silver nanoparticles in the marine polychaete, Hediste (Nereis) diversicolor**
Y Cong, GT Banta, H Selck, VE Forbes
Roskilde University, ROSKILDE, Denmark
Silver nanoparticles (Ag NPs) are of concern due to their increasing use in consumer products which may pose risks for the aquatic environment. In this study, the toxicities of commercial PVP-coated Ag NPs (20 and 80 nm) on the marine sediment-dwelling polychaete, *Hediste (Nereis) diversicolor*, were compared with ionic-Ag ($AgNO_3$) after 10 d of sediment exposure, using burrowing behavior, lysosomal stability, DNA damage (comet assay) and bioaccumulation as endpoints. The nominal concentrations used in exposure scenarios were 0, 5, 10, 25, 50, 100 µg Ag/g dry weight (dw) sediment. Our results show that Ag is able to cause DNA damage and instability of lysosomal membranes in in *H. diversicolor* coelomocytes and that, this effect is related to both Ag concentration and form. Ag NPs tend to be more toxic than the ionic form. No toxicity of PVP coatings was observed. Ag body burden increased with increasing exposure concentration of both Ag forms, indicating that they are bioavailable to *H. diversicolor*. Further studies are currently being conducted to investigate if the bioaccumulation is also size-dependent, as well as to assess the effects of Ag NPs and Ag+ ions on burrowing behavior. Results from this work will also be presented.

**NM02C-2**
**Chronic effects of nanosilver to *Daphnia magna*gt**
C Voelker, S Giebner, D Kaiser, M Oetken, J Oehlmann
Goethe University, FRANKFURT, Germany
Nanoscale silver is one of the most promising nanomaterials for various future applications. Due to its antibacterial properties nanosilver is increasingly employed in a variety of consumer products including wound dressings, textiles, personal care products, paints, or food storage containers. Currently, no data exists for environmental concentrations, but the incremental production of nanosilver inevitably leads to an increased environmental release. Several studies have demonstrated the toxicity of nanosilver to different species of bacteria, suggesting that these effects may be detrimental to aquatic ecosystems. Potential routes of uptake by aquatic organisms include direct ingestion or entry across epithelial boundaries such as gills or body wall. Toxicity and exposure data for aquatic invertebrates, however, is currently lacking. There are only few studies on the acute toxicity of nanosilver. Long dose and long-term invertebrate exposures giving priority to sublethal effects provide useful completion.
The aim of this study is to evaluate the chronic toxicity of nanoscale silver on *Daphnia magna*. The effects on growth, reproduction, and viability were assessed in a multi-generational study. Particle size and shape were characterised by dynamic light scattering using a zeta sizer and transmission electron microscopy.
The results show that with increased exposure duration the toxicity of nanosilver to *D. magna* increases. The exposure of consecutive generations of *D. magna* results in an effective concentration (LOEC/2=0.75 µg L-1) about ten times lower compared to the 21-d reproduction test (NOEC=6 µg L-1). Therefore, long-term studies should be given a high priority to make an adequate evaluation of the potential environmental risks of nanosilver and nanomaterials in general.

**NM02C-3**
**Do TiO2 nanoparticles affect earthworm reproduction?**
K Hund-Rinke[1], K Schlich[2], K Terytze[3]
[1]Fraunhofer Institute for Molecular Biology and Applied Ecology, SCHMALLENBERG, Germany
[2]Fraunhofer Instiute for Molecular Biology and Applied Ecology, SCHMALLENBERG, Germany
[3]Freie Universität Berlin, BERLIN, Germany
The toxicity of three different TiO2 nanoparticles was investigated in the earthworm reproduction test according to the OECD test guideline No. 222. All applied nanoparticles were derived from the OECD-Sponsorship Programme and differed in parameters such as primary particle size, crystalline structure, BET surface and zeta potential. The tests were performed in a natural sandy soil. TiO2 was applied via powder in the soil simulating an atmospheric immission. In preliminary experiments the homogenous distribution of the particles via this procedure was demonstrated. Suitable amounts of TiO2 powder to achieve the desired final soil content were mixed homogenously with dry soil. Care was taken to avoid the modification of the TiO2 crystalline structure. Uncontaminated sandy soil was spread on a plate, the carrier material with the TiO2 powder distributed on the soil, and the whole material was mixed carefully. The water content was adjusted to 55% of the maximum water-holding capacity. Test concentrations were: 50, 100 and 200 mg/kg soil dry matter.
No influence on the biomass of adults was observed, but the reproduction rate was significantly increased. A maximum stimulation of about 50% was observed. The extent of stimulation differed between the three nanoparticles. Unexpectedly, the nanomaterial with the largest primary particle size and a small surface resulted in the maximum effect. Experience so far indicates that a small primary particle size and a large surface result in increased toxicity. Looking at the total number of the offspring and not at the percent effect leads to an interesting observation. The number of offspring in the control was lower in winter, increasing in summer. Such an increase in the number of offspring was not observed in the containers with TiO2. Over the testing period of several months the number of offspring of earthworms exposed to TiO2 contaminated soil varied to a much lower extent than the number of offspring of earthworms incubated in control soil. Usually the reproduction rate of Eisenia andrei - even of those earthworms cultured in the laboratory since many years - shows a seasonal variation. A nearly constant reproduction rate throughout a year could be the consequence of a disturbance of the circannual biological rhythm by TiO2. Further experiments have to verify the hypothesis.

**NM02C-4**
**Comparing the reproductive toxicity of ZnO nanoparticles, bulk ZnO, and ZnCl2 to the earthworm Eisenia andrei**
LR Heggelund[1], N Cedergreen[1], C Svendsen[2], D Spurgeon[2]
[1]Copenhagen University, FREDERIKSBERG, Denmark
[2]Centre for Ecology and Hydrology, CROWMARSH GIFFORD, WALLINGFORD, United Kingdom
Nanotechnology is developing very fast and industrial applications are many. Zinc oxide (ZnO) nanoparticles (NPs) are widely used in consumer products e.g. as UV protecting agent and can be expected to enter the environment via sewage sludge applied to soils. ZnO NPs are some of the most toxic in aquatic exposures, but investigations of their effects in terrestrial systems are lacking. These circumstances make the study of NP zinc oxide in terrestrial ecosystems very relevant. It is known that zinc can have negative effects on life-cycle responses in the earthworm E. fetida, but the comparative effects of nano and non-nano or dissolved zinc in soil have not yet been investigated in detail. In this study we compared the reproductive toxicities of NP, bulk (non-nano) and dissolved Zn to the earthworm Eisenia andrei. The main results of the experiment were: 1) ZnCl2 toxicity was greater than NP and bulk Zn forms and 2) the reproduction rate was the most sensitive endpoint in the experiment, since it was affected by all forms of Zn. The estimated LC50 values for ZnCl2 (1436 mg/kg week two, 1235 mg/kg week four) and the reproduction rates recorded in this experiment are comparable with other studies. The results supported the general consensus that toxicity of ZnO NPs to earthworms is determined by the amount of free zinc ions and they also suggested that the nanoparticle agglomeration and adsorption behaviour in the soil affected the bioavailability to the worms. In light of the present results it is likely that the risk assessment of ZnO NP in the environment does not need to go beyond the one of dissolved zinc.

**NM02C-5**
**Ecotoxicity of ZnO-NP, bulk ZnO and ZnCl2 to Folsomia candida in relation to bioavailability in soil**
PL Kool, M Diez Ortiz, CAM van Gestel
Vrije Universiteit, AMSTERDAM, The Netherlands
Only nine ecotoxicological studies are available to assess the effects of metal nanoparticles on soil organisms. Most inorganic nanoparticles are tested in aquatic systems, while the ecotoxicity of

the majority is not assessed in soil. Due to adsorption and dissolution of nanoparticles the toxicity of metal nanoparticles in soil is difficult to establish. The present study aims to determine the chronic toxicity of zinc oxide nanoparticles (ZnO-NP) to Folsomia candida, by studying survival and reproduction in freshly spiked soil. To unravel the contribution of zinc oxide particle size and free zinc to nanoparticle toxicity, bulk ZnO (i.e. non-nano) and ZnCl2 are tested for comparison. Toxicity tests were performed in natural Lufa 2.2 soil using standard test procedures as described in ISO guideline 11267.
For all three compounds, zinc concentrations in the porewater increased with increasing soil concentrations. This is reflected by the Freundlich isotherm yielding sorption constants Kf of 61.7, 106 and 96.4 l/kg (with corresponding n values of 1.50, 1.34 and 0.42) for ZnO-NP, bulk ZnO and ZnCl2 respectively.
Survival of F. candida in soil spiked at concentrations up to 6400 mg Zn/kg d.w. with ZnO-NP and bulk ZnO was not affected. Reproduction was reduced in a dose-dependent manner and 28-d EC50 values of 1964, 1591 and 298 mg Zn/kg d.w. were estimated for ZnO-NP, bulk ZnO and ZnCl2, respectively. It seems that the size of zinc oxide particles does not contribute to a significant difference in the effect observed on springtail reproduction. Compared to ZnCl2, the EC50 of ZnO-NP based on actual zinc concentration in soil was almost 7-fold higher, but the difference in EC50 values is small when based on porewater concentrations. EC50 values of 10.1, 7.94 and 16.8 mg Zn/l were calculated for ZnO-NP, bulk ZnO and ZnCl2, respectively based on measured concentrations in the soil pore water.
We conclude that ZnO particle size does not affect the reproduction of the soil organism F. candida. It is very likely that the zinc ions released from the nanoparticles are responsible for the observed toxic effects rather than the nanoparticles as such.

**NM02C-6**

**In vitro nanotoxicology bridges earthworms and humans: comparative analyses of the molecular and cellular toxicity**

Y Hayashi[1], P Engelmann[2], R Foldbjerg[1], M Szabó[2], LL Mácsik[2], D Sutherland[1], H Autrup[1], J Scott-Fordsmand[1], LH Heckmann[1]
[1]Aarhus University, AARHUC C, Denmark
[2]University of Pécs, PÉCS, Hungary

Silver nanoparticles (AgNPs) are among the most widely used materials in commercial nanoproducts and as a potential tool for biomedical application. Still, little is known about their immunological consequences. Invertebrate models have long been exploited to study the evolutionary development of innate immunity by cross-referencing to more complex human immune systems. Here we illustrate our initial approach to compare the gene and cellular responses of earthworm coelomocytes and human immunocytes to silver ions ($Ag^+$) and AgNPs *in vitro*. One-step conjugation of AgNPs with serum albumin provided extensive colloidal stability, and the AgNP suspension was sterically stable over time under the test condition, with a free $Ag^+$ fraction of <1%. Cell viability, oxidative stress and gene expressions of coelomocytes and human cells were assessed following exposure to $Ag^+$ (0 - 1.35 μg/ml) or AgNPs (0 - 5.91 μg/ml). Earthworm coelomocytes were more sensitive to $Ag^+$ than the human immunocytes (THP-1 monocytes, THP-1 macrophages and human peripheral blood mononuclear cells). Coelomocytes were also most susceptible to AgNPs while $EC_{50}$ values for THP-1 monocytes and macrophages could not be estimated within the concentration range tested. Remarkably, though, the dose-response curve of THP-1 macrophages for the AgNP treatment was similar to that of coelomocytes. Furthermore, we observed a strikingly similar time-course pattern for the increase in intracellular generation of reactive oxygen species (ROS) between coelomocytes and THP-1 monocytes exposed to $Ag^+$ or AgNPs. Following AgNP exposure, genes involved in innate immune systems, metal detoxification and anti-oxidising mechanisms showed similar responses between coelomocytes and THP-1 monocytes suggesting that these molecular pathways are potentially affected by the interference of AgNPs with the cellular machinery. Progressive induction of some of the genes observed in our in vitro assays is also reported in a separate study on temporal molecular toxicity of AgNPs to whole worms in soil (Heckmann et al. in prep), supporting the importance of those genes for the defence mechanisms against AgNPs. With the aid of *in vitro* techniques, our comparative approach begins to provide exciting insights into the conserved molecular and cellular mechanisms of NP toxicity between invertebrates and vertebrates.

**NM02D-1**

**Interaction of nanosized Poly (amido) amine dendrimers with fresh water ecological organisms and fish cells**

PC Naha, MD Davoren, HJ Byrne
Dublin Institute of Technology, DUBLIN, Ireland

Nanotechnology is a highly promising and exciting technology that spans many areas of science and technological applications. Polymeric nanomaterials are widely used in different aspects of the medical field in terms of diagnosis, tissue engineering and as drug delivery devices. As nanomaterials are currently being widely used in modern technology, there is an increasing need for information regarding their human health and environment. This study focussed on the eco and mammalian toxicological impact of three generation of poly-amidoamine (PAMAM) dendrimers (G-4, G-5 and G-6) on a battery of bioassays representing different trophic levels for the ecotoxicological study. The acute eco and cytotoxicological effects of poly-amidoamine (PAMAM) dendrimers (G-4, G-5 and G-6) were evaluated in a bacterial species (Vibrio fischeri), unicellular algae (Pseudokirchneriella subcapitata), two crustaceans (Thamnocephalus platyurus and Daphnia magna) followed by cytotoxicity assessment with two different fish cells (RTG-2 and PLHC-1) to represent vertebrate species. The ecotoxicity results demonstrate that there is systematic generation dependent ecotoxicological [1]. The origin and molecular mechanism of toxicological response due to the exposure of PAMAM dendrimers was explored with fish cell (PLHC-1). Toxicity of the PAMAM dendrimers starts with generation of reactive oxygen species [2], and then lead to DNA damage and apoptosis will be discussed.
Key Words: PAMAM dendrimers; Ecotoxicology; Cytotoxicity; Oxidative stress; DNA damage; apoptosis.

**Developmental toxicity of metal oxide nanoparticles on Xenopus laevis: focus on the disruption of the intestinal barrier**

P Mantecca[1], R Bacchetta[2], E Moschini[1], N Santo[2], U Fascio[2], M Camatini[1]
[1]University of Milano Bicocca, MILAN, Italy
[2]University of Milan, MILAN, Italy

Despite the huge amount and rapidly increasing data on the toxicological properties of nanomaterials, the ecotoxicological threatening of such contaminants is far to be characterized. In particular aquatic ecosystems, representing a terminal receptor of nano-contaminants and a realistic accumulation site, merit more attention.
This work contributes to the knowledge of the potential adverse developmental effects inducible by metal oxide nanoparticles (NPs) on amphibian embryos. Lethal and teratogenic potentials of commercially available ZnO, CuO, TiO2 NPs (nZnO, nCuO, nTiO2) were characterized for their hydrodynamic behaviour and tested on standardized FETAX procedure. Embryos were histologically screened to detect lesions in primary organs. No mortality was observed after NPs' exposure, while a significant concentration-dependent growth retardation was induced especially by nCuO. Moreover nCuO resulted to be a powerful teratogen, with survived embryos characterized by diffuse severe malformations. nZnO did not induce severe teratogenic effects, while at histological and ultrastructural levels intestinal mucosa showed diffuse lesions.
At comparable nominal dimensions and mass concentration, metal oxide NPs produced different effects on Xenopus development, confirming that toxicity depends on both ion dissociation and particles themselves reactivity. nCuO embryotoxicity mainly derived from dissolved copper ions, while that of nZnO was apparently associated to the NP reactivity.
The NPs tested entered the gut epithelium, producing additional teratogenic potentials in late developmental stages, by an alteration of the intestinal physiology or a NP translocation through other organs. The imaging techniques evidenced the presence of NPs beyond the intestinal lumen, in the surrounding connective tissue and even in many non-target organs.
While for nCuO and nTiO2 no conclusive indications about their teratogenic mechanisms of action have yet emerged, our experimental data support the hypothesis that nZnO can sneak into the paracellular space, reaching the basement membrane. This mechanism probably involves intestinal cell injuries leading to cytoskeletal rearrangements, responsible of the possible disruption of the tight junctions.
In conclusion, the comparative study of the embryotoxic potential of three widely used metal oxide NPs, suggests that different mechanisms drive the toxic effects and the translocation pathways.

**Aquatic toxicity and characterisation of carbon nanotubes in amphibian larvae Xenopus laevis**

F Mouchet[1], LG Gauthier[1], FM Mouchet[1], FB Bourdiol[1], AP Perrault[1], PP Puech[2], EF Flahaut[3], CG Gancet[4], JCB Boutonnet[4], EP Pinelli[1]
[1]ECOLAB, CASTANET TOLOSANE, France
[2]CEMES, TOULOUSE, France
[3]CIRIMAT, TOULOUSE, France
[4]ARKEMA, LACQ, France

Carbon Nanotubes (CNTs) are already used in some commercial applications. The question of their release in the environment occurring during life cycle of manufactured product containing CNTs may soon become relevant. Nevertheless, little is known about their potential ecotoxicity. Investigations of their environmental hazard were conducted in the framework of the Joint Research Laboratory NAUTILE (Nanotubes & Ecotoxicology). Two kinds of CNTs, synthesized using similar processes (Catalytic Chemical Vapour Deposition), but very different in nature, were studied: double-walled nanotubes (DWNT, CIRIMAT) and multi-walled nanotubes (MWNT, Graphistrength C100, Arkema France).
The present study examines the potential impacts of CNT in the aquatic environment, since this compartment could be the ultimate receptacle of contamination, depending on their emission scenarios, thus making the aquatic assessment of nanoparticles of particular importance.
The tools which were carried out have helped us to push the investigation towards sensitive biological models such as amphibian larvae (Xenopus laevis), using international standardized bioassays (IS0, 2006). For a given type of CNT, raw and chemically dispersed CNTs have been added to the exposure media, using surfactants, to assess biological variations in relation with their physical dispersion state. Two different endpoints were assessed: (i) toxicity (mortality and growth inhibition) and (ii) genotoxicity (induction of micronucleated erythrocytes). In addition, biological preparations of amphibian organs from larvae exposed to CNTs were analyzed using optic microscopy, Transmission electron microscopy and Raman spectroscopy.
The results show growth inhibition in larvae exposed to 10 and 50 mg.L-1 of raw CNT. Modulated effects on growth parameter were obtained in organisms exposed in presence of surfactant. No genotoxicity was evidenced in erythrocytes of larvae exposed to CNT, except with one of test conditions in presence of surfactant. The Raman analysis confirmed the presence of raw CNT into the lumen of gut larvae but not in intestinal tissues and cells, nor in the circulating blood of exposed larvae.
These data strongly support that the chronic toxicity observed in larvae exposed to high concentrations of CNT could be due to physical effects (gill clogging and/or abrasive effects) which are not necessarily related to intrinsic effects of individual CNT.

**NM02D-4**

**Rusting of the Trojan horse - Kinetics and mechanisms of ion release from nano-silver surfaces**

J Liu, DA Sonshine, S Shervani, RH Hurt
Brown University, PROVIDENCE, United States of America

Nano-silver (nAg) is being manufactured at large scale and incorporated into various consumer and medical products as a broad-spectrum antimicrobial agent. The high production volume raises concern about silver release to the environment and potential adverse impacts on human health and environment. The major pathways in the antibacterial activity, eukaryotic toxicity and aquatic toxicity of nAg involve the silver cation - Ag+, which is an established thiol toxicant. In these ion-based toxicity pathways, nAg particles act as a "Trojan Horse", a reservoir of metallic silver that can be delivered to biological targets and released as active Ag+ ions. This talk focuses on the origin of Ag+ in nAg particle suspensions. The ion release is shown to be a cooperative oxidation process requiring both dissolved O2 and H+, and to be inhibited by natural organic matter. Both data and thermodynamic modeling indicate that metallic nAg will not be a persistent toxicant in particle form in environmental compartments containing O2. Understanding ion release mechanisms allow a drug delivery paradigm to be applied to the nAg system, in which various chemical approaches are used to achieve controlled release formulations. After presenting thermodynamic calculations of silver species partitioning in biological media, the rates of oxidative silver dissolution are measured for nanoparticles and macroscopic foils and used to derive unified area-based release kinetics. A variety of competing chemical approaches are demonstrated for controlling the ion release rate over 4 orders of magnitude. Release can be systematically slowed by thiol and citrate ligand binding, formation of sulfidic coatings, or the scavenging of peroxy-intermediates. Release can be accelerated by pre-oxidation or particle size reduction, while polymer coatings with complexation sites alter the release profile by storing and releasing inventories of surface-bound silver. The ability to tune biological activity is demonstrated through a bacterial inhibition zone assay carried out on selected formulations of controlled release nAg. Our results have important implications for the fate and transport of nAg in the environment and in biological systems. Ion release kinetics is proposed that can be incorporated into quantitative environmental fate and transport models. Finally, the ability to control ion release rate will allow optimization of nAg-based antibacterial products for performance, lifetime, and safety.

**Engineered nanoparticles as toxic metal carriers in the aquatic systems: quantum dots like Cu and Pb nanovectors**

VI Slaveykova[1], I Worms[2]
[1]University of Geneva, VERSOIX, GENEVA, Switzerland
[2]Ecole Polytechnique Fédérale de Lausanne (EPFL), LAUSANNE, Switzerland

Despite of the expected enhanced surface properties, there is a paucity of data concerning the role of the engineered nanoparticles as trace elements carriers. By exploring the capabilities of the multidetection instrumental platform consisting of asymmetrical flow field-flow fractionation coupled in-line to UV spectrometry and inductive coupled plasma mass spectrometry, the present study examines the role of the carboxyl-terminal group polymer coated CdSe/ZnS quantum dots (QDs) as a potential nanovectors of toxic trace elements in the aquatic systems. More specifically the size and elemental distributions was probed by quantifying the association of Cu and Pb as a function of the size distribution, as well as the effect of the Suwannee River fulvic (SRFA) or humic (SRHA) acids, representing the dissolved organic matter in waters.

Obtained results showed a monodisperse distribution of quantum dots with average hydrodynamic diameter of 12.8 ± 0.5 nm. Addition of both 20 mg $L^{-1}$ SRFA, or SRHA, and 100 µg $L^{-1}$ of Cu and Pb did not significantly influence the QDs hydrodynamic size distributions. The amount of Cu and Pb bound to the Qdots was three times larger than that associated to fulvic and humic acids In the ternary system containing metals, humic acids and QDs, the amount of Cu or Pb bound to the QDs was 12 and 5 times higher than that associated to the SRFA or SRHA, respectively. These observations suggest that QDs bind Cu and Pb to a larger extent than SRFA and SRFA and have the extended potential to play a role of metal vector in the environment. The environmental implications of the results are discussed with respect to the transport of trace metals in the environment as well as their consequence for bioavailability and potential biological effects.

**NM02D-6**

**Heterocoagulation of silver nanoparticles**

GFH Cornelis[1], JK Kirby[2], D Chittleborough[1], MJ Mclaughlin[2]
[1]University of Adelaide, GLEN OSMOND, Australia
[2]CSIRO Land and Water, URRBRAE, Australia

Increasing exposure of the enviroment to silver nanoparticles (AgNP) has raised concern because of possible ecotoxicity. However, the transport mechnanisms of AgNP are not clear, but there are indications that heterocoagulation of AgNP with naturally occuring colloids may be important. This study investigates, for the first time, heterocoagulation of PVP-coated AgNP (10 nm nominal diameter) with maghemite (Fe2O3, < 50 nm nominal diamter) and montmorrillonite (135 nm hydrodynamic diameter) at pH 4 and pH 8 as a function of increasing NaClO4 concentration. Coagulation rates of AgNP in individual suspensions were relatively low, with critical coagulation concentrations of 21 and 45 mmol L-1 at pH 4 and 8, respectively. However, aggregation rates increased with several orders of magnitude in AgNP - maghemite mixtures at pH 4, regardless of NaClO4 concentration. In the case of AgNP - montmorillonite mixures, the rate increase relative to indiviudal suspensions was significant, but less compared to mixtures with maghemite. Simialrly, rate increases were much less in all cases at pH 8. This study suggests that heterocoagulation with natural colloids may be an important mechanism that controls the fate of AgNP and other engineered nanoparticles in the environment, particularly in relatively acidic soils and natural waters with a low ionic strength.

## NM03 - Risk assessment and risk management of nanomaterials

**NM03-1**

**Engineered nanomaterials in rivers - exposure scenarios for Switzerland at high spatial resolution for nano-TiO2, nano-ZnO and nano-Ag**

F Gottschalk[1], Ch Ort[2], R Scholz[3], B Nowack[4]
[1]EMPA, ST. GALLEN, Switzerland
[2]The University of Queensland, Advanced Water Management Centre (AWMC), QLD 4072, Australia
[3]ETH Zurich, Institute for Environmental Decisions, Natural and Social Science I, ZÜRICH, Switzerland
[4]Empa - Swiss Federal Laboratories for Materials Science and Technology, Technol, 9014 ST. GALLEN, Switzerland

Two models, one based on probabilistic material flow analysis and one based on graph theory, were combined to calculate predicted environmental concentrations (PECs) of engineered nanomaterials (ENMs) in Swiss rivers at high spatial resolution. PECs for nano-$TiO_2$, nano-ZnO and nano-Ag were calculated for 543 river sections downstream from 543 sewage treatment plants at base flow conditions. Additionally, flow measurements at 20 selected locations over a 20-year period (1988-2007) were used to assess temporal variations. Two scenarios were modeled - a reactive scenario considering ENM agglomeration/ degradation/sedimentation in aqueous systems and a conservative scenario assuming no ENM transformation. At base flow the highest PECs were found for nano-$TiO_2$: The PECs ranged, depending on the location, from 0.1 ng $L^{-1}$ to 7,800 ng $L^{-1}$modal values), followed by nano-ZnO (0.004 ng $L^{-1}$ to 500 ng $L^{-1}$) and nano-Ag (0.2 pg $L^{-1}$ to 32,500 pg $L^{-1}$). This study shows that linking a probabilistic material flow analysis to a geo-referenced model fills two gaps: (i) considering the geographical distribution of the ENM emissions and local river flow rates allows for a prediction of a more realistic range of possible environmental concentrations than at a regional level; (ii) a clear distinction between input uncertainty and river flow variations can be achieved. Temporal river flow variations influenced the ENM concentrations up to a factor of 10 - when considering the 15%-85% quantiles of flow - the uncertainty in the ENM loads caused a difference in the PEC calculations up to a factor of 5 - considering the same quantiles for ENM emissions.

**NM03-2**

**A way forward in exposure assessment of nanomaterials in the aquatic environment**

TK Quik[1], A Vonk[1], S Foss Hansen[2], A Baun[2], D van de Meent[3]
[1]National Institute for Public Health and the Environment (RIVM), BILTHOVEN, The Netherlands
[2]DTU Environment, Technical University of Denmark, LYNGBY, Denmark
[3]Radboud University Nijmegen, Institute for Wetland and Water Research, NIJMEGEN, The Netherlands

The current approach to ecological risk assessment of chemicals is based on the quotient of a predicted no effect concentration and a predicted exposure concentration. We have gathered knowledge supporting the prediction of the exposure concentration of nanomaterials (NMs) in the aquatic environment and have evaluated the adequacy of the current guidance documents for use with NMs and therefore have also conducted a literature review on two important environmental fate processes for NMs, sedimentation and dissolution. This resulted in an overview of the available quantitative data for sedimentation and dissolution of NMs. We have used this overview to propose a way forward in modeling the exposure concentration of NMs in the water phase. Transport to sediment seems to be of greater relative importance than advection or dissolution of NMs. Both the transport of nanomaterials from water to sediment and the dissolution of nanomaterials can be incorporated into current exposure models simply by adding first-order rate constants. Our proposed exposure model for nanomaterials can be used to improve current risk assessment for nanomaterials.

**NM03-3**

**Developing exposure scenarios for manufactured nanomaterials: knowledge gaps and research needs**

JA van Tongeren[1], K Clark[2], D Brouwer[3], F Christensen[4], B Nowack[5], F Gottschalk[5], S Friedrichs[6], K Schmid[1], S Peters[1], R Aitken[1], C Vaquero[7], V Gkanis[8], R Gerritsen[3], M Riediker[2]

[3]TNO, ZEIST, The Netherlands
[4]JRC, ISPRA, Italy
[5]EMPA, ST. GALLEN, Switzerland
[6]NIA, BRUSSELS, Belgium
[7]LEIA, MIÑANO, Spain
[8]Demokritos, ATHENS, Greece

The introduction of manufactured nanomaterials (MNMs) and products enhanced by MNMs onto the global market is developing at a rapid pace and this means that the potential for human and environmental exposure is also increasing. Exposure assessment for MNMs is a specialised field that requires the use of advanced instruments and specialised expertise and it will often not be feasible for companies to measure exposures. For risk assessments for MNMs it is essential that information on exposure is shared between scientists and organisations. The NANEX project was funded by the European Commission to try to develop a catalogue of exposure scenarios (ESs) for MNMs based on publicly available information as well as information collected during measurement surveys. The results were used to carry out a gap analysis and determine research priorities. The focus was on exposure to carbon nanotubes (CNTs), nano-silver (nano-Ag) and nano titanium dioxide (nano-TiO2).

In total, 57 occupational ESs were developed; including 28 for CNT, 13 for nano-TiO2 and 4 for nano-Ag. Most of the scenarios were related to production/synthesis of the nanoparticles, although some were also developed for downstream use. For consumer exposure, there was a paucity of information and consumer ESs developed were based on very limited information.

There is a critical lack of exposure information available in the public domain, and any available exposure data are generally presented in a way that they are difficult to interpret and use for 'read-across' to similar ESs. Some level of harmonization of reporting of results of exposure measurements and contextual information is urgently needed. The NANEX project suggested a minimum dataset for reporting exposure studies for MNMs, which includes both nano-specific and more general items. One important realisastion is that exposure to MNMs is multi-factorial, and it cannot currently be described satisfactory by a single exposure metric. A white paper on research priorities for exposure assessment to MNMs is under development. The shortterm priorities include development of efficient risk management strategies, development of sampling instruments and measurement methods and harmonization of characterisation and quantification of exposures. The medium- and long-term research priroities include the study of determinants and modifying factors for the various relevant exposure metrics and development of quantitative exposure models.

**NM03-4**

**A weight of evidence methodology for risk assessment of engineered nanomaterials**

DR Hristozov, SG Gottardo, AC Critto, AM Marcomini
Ca Foscari University of Venice, VENICE, Italy

The production and use of engineered nanomaterials (ENMs) are addressed by the European REACH regulation ð'- 1907/2006, which gives industries the responsibility of the Chemical Safety Assessment (CSA) for any produced or imported industrial substance. The required CSA follows the traditional risk assessment (RA) framework, including hazard assessment, exposure assessment and risk characterisation steps. It has been recognized, however, that substantial limitations and uncertainties make the conventional RA infeasible to apply to ENMs today, which leaves regulators with little support in the near term. Knowledge gaps have been gradually filled by new research results and uncertainties have been reduced, but this process advances slowly and it will take decades [1], while quantitative risk assessment results are urgently needed to support timely regulatory decisions and risk management actions [2]. In response to this need, a number of methodologies and tools to assess the risks from ENMs, in spite of the limitations, have been proposed. Most of them, however, are not intended to facilitate regulatory decision making, but instead to serve as preliminary hazard/risk screening and/or research prioritization tools. The present deficit of quantitative data and scientifically sound approaches will lead in the near and in the medium terms to uncertain and ambiguous, largely qualitative risk estimations based on expert judgments, which may fail to support proper risk management actions. Therefore it is important to study the possibilities to aid the traditional RA framework with complementary/alternative tools in an attempt to achieve quantitative RA of ENMs. In this context a novel approach for RA and prioritization of ENMs, including uncertainty evaluation, is being developed within the FP7-funded ENPRA project. The main goal of the proposed methodology is to quantitatively assess and rank human health risks due to exposure to ENMs in occupational and/or consumer settings. This presentation will illustrate the novel ENPRA approach in the context of the feasibility of available methodologies and tools for risk assessment of ENMs and will discuss its implications for ENM risk management and regulation.

**NM03-5**

**A comprehensive environmental assessment approach to making informed decisions about engineered nanoparticles**

R Johnson, S Griggs, A Steevens
US Army Engineer Research & Development Center, VICKSBURG, United States of America

Metal-based nanoparticles are being developed in numerous shapes and sizes to fit a wide array of consumer, industrial, and military applications. Material science research into the development of new nanoparticles is far outpacing environmental and human health and safety research, yet the health and safety data are critical for acquisition decisions, regulatory decisions, worker safety, product use and disposal, and public acceptance of nanoparticle-containing products. Traditional life cycle analyses address key steps in nanoparticle synthesis, use, and disposal, but lacks specific information regarding fate and effects in the environment. Conversely, traditional environmental risk assessment addresses fate and effects of chemical stressors in the environment, but only considers chemical that goes into the environment and does not take into consideration the entire chemical stock from the manufacturer. Therefore, we propose using a comprehensive environmental assessment (CEA) approach, detailed by Davis (2007) to evaluating nanoparticles from "cradle to grave". CEA combines life cycle analysis parameters (e.g., manufacture, storage, use, disposal) with traditional risk assessment parameters (e.g., characterization, exposure, effects, assessment) to give a more comprehensive understanding of nanoparticle exposure and effects in different environmental settings. We will use aluminum nanoparticles as a case study. By applying the CEA approach, we can better assess for a manufacturer or acquisition authority the key aspects of the Al nanoparticle life cycle that will pose a potential impact on environmental processes and health effects. It will also help identify data gaps that need to be addressed prior to acquisition or risk management decisions. In conclusion, the use for CEA for nanoparticles will improve acquisition, risk, and regulatory decision making and management prior to any unforeseen adverse environment, health, and safety (EHS) events that could dramatically impact the use of these revolutionary new materials.

**NM03-6**

**Decision-directed approach to EHS strategy for nanomaterials**

I Linkov[1], M Bates[1], J Keisler[2], T Seager[3]
[1]US Army Engineer R&D Center, CONCORD, United States of America
[2]University of Massachussets, BOSTON, United States of America
[3]Arizona State University, TEMPE, United States of America

The recent emergence of nanotechnology in both the marketplace and the public consciousness coincides with increased recognition of the importance of an integrated, systems approach to environmental, health and safety that includes life-cycle thinking, public participation, and adaptive management of risks associated with emerging technologies and chemicals. As a result, environmental research strategy documents like those published by the US Environmental Protection Agency (EPA) and the National Nanotechnology Initiative (NNI) emphasize a broad, comprehensive approach that includes identifying nanomaterial source terms at all stages of the nanomaterial life-cycle, characterization of environmental fate and transport properties, identification of toxic and abiotic effects, and pre-emptive engineering of novel materials to overcome anticipated public or stakeholder objections. Nevertheless, the same federal agencies that have advocated for such forward-thinking approaches have been criticized for failing to articulate a strategy and framework for effectively linking environmental risk research to the decision-making needs of product developers, regulators, consumers or other stakeholder groups. Two analytic approaches that have yet to be sufficiently integrated can provide a powerful approach to better connecting the nanotechnology research agenda with product developer, policy-maker, or consumer decision needs: value of information (VoI) and multi-criteria decision analysis (MCDA). VoI explores the sensitivity of a decision under uncertainty to new information before making a decision, while MCDA allows comparison of decision alternatives that are not reducible to a single criterion (such as cost-benefit analysis). Both MCDA and VoI have been used successfully in industry and have attracted increasing attention in government and regulatory applications. However, actual implementation in public sector is still rare. This presentation will provide methodology and illustrate applications of VOI and MCDA to enhance risk assessment for nanomaterials. Implications for nanomaterial EHS risk governance will be discussed.

## PE01 - Data-driven, knowledge-based, and QSAR modelling in ecotoxicological assessment

**PE01-1**

**Who needs lab work? An investigation into predictive ecotoxicological computer models and naphthenic acids.**

DEA Jones, SJ Rowland, A Scarlett, C West
Biogeochemistry Centre, PLYMOUTH, United Kingdom

Computer based predictive ecotoxicology models are increasingly used to assess adverse effects of chemicals that are released into the environment. Ease of use and cost effectiveness makes these models attractive alternatives to field and laboratory testing.

In the present study the toxic effects of individual carboxylic ('naphthenic') acids were determined by two predictive quantitative structure activity relationship computer models (ECOSAR v.1.00a and ADMET v. 5.0). In the case of ECOSAR some physiochemical parameters, and toxicity to fish, algae and crustaceans were predicted. ADMET is a more detailed model based on human toxicity and provides physiochemical parameters, enzyme metabolism, human liver effects, mutagenicity as well as some ecotoxicological predictions.

The so called 'naphthenic' acids are a group of compounds that are of increasing concern due to their presence within oil industry waste, including oil sands process waters. Few of these compounds are commercially available and have to specially synthesised so predictive models may be helpful for targeting specific structures for synthesis.

Toxicity predictions for the effects of the acids on *Tetrahymena pyriformis* from the ADMET model and on *Daphnia magna* from ECOSAR were compared to measured Microtox[TRADEMARK] bacterial assay results for *Vibrio fisherii*. For an investigation of possible quantitative structure activity relationships acids were grouped into classes (e.g. aliphatic, aromatic).

Both models produced statistically significant trends ($p = <0.01$ and $<0.001x$ to y; $R^2= 0.2292$ and 0.4323) against the Microtox[TRADEMARK] tested data for some series of acids but neither distinguished between the effects of isomeric acids (e.g. iso, tertiary and secondary alkyl substituted acids).

Predictive models may be used to target work on potentially toxic chemicals that are released into the environment but it is recommended that any data obtained from them are verified by thorough laboratory based testing.

**PE01-2**

**A combined expert knowledge and data-driven approach to predict biotransformation pathways of organic contaminants**

K Fenner[1], DE Helbling[1], S Kramer[2], LBM Ellis[3], L Wackett[3]
[1]Eawag, DÜBENDORF, Switzerland
[2]Technische Universität München, GARCHING B. MÜNCHEN, Germany
[3]University of Minnesota, MINNEAPOLIS, United States of America

In silico systems that predict plausible structures of transformation products (TP) formed through microbial transformation of xenobiotics could play an important role in obtaining a more comprehensive picture of environmental exposure to TPs. Lists of predicted TP structures can be used to screen environmental samples for TPs or for model-based prioritization of plausible TPs at the first tiers of chemical risk assessment. Existing rule-based expert systems that predict biotransformation pathways typically suffer from low selectivity, i.e., many more products are predicted than are experimentally observed. This often prevents their application, e.g., to support inclusion of TPs into chemical risk assessment. Here, we present two data-driven approaches to increase the selectivity of rule-based biotransformation pathway prediction and demonstrate how their implementation increased the selectivity in one specific rule-based system, the University of Minnesota Pathway Prediction System (UM-PPS) (http://umbbd.msi.umn.edu/predict/). The approaches include the data-driven extraction of relative reasoning rules from data contained in the University on Minnesota Biocatalysis/Biodegradation Database (UM-BBD), a manually maintained collection of literature-reported biotransformation pathways, and the targeted generation and analysis of experimental biodegradation data for pertinent transformation rules. Implementation of relative reasoning rules reduced the number of predicted first generation TPs by about 50%, increasing selectivity from 10 to 20%. At the same time, the percentage of correctly predicted, experimentally observed products slightly decreased for external validation, demonstrating that uncertainty and heterogeneity in the training and validation data limit optimization in rule-based systems. For the investigation of pertinent transformation rules, a combined experimental, analytical, and data processing procedure was developed for the high-throughput identification of TPs formed in sludge-seeded bioreactors. The approach was applied to refine transformation rules for the amide functional group by investigating transformation pathways of 30 diverse amides. Altogether 53 TPs were identified and the data were analyzed in terms of electronic and steric features dictating the observed transformation pathways. A metabolic logic for the preferred biotransformation pathways of amides was derived that has been implemented into UM-PPS.

**PE01-3**

**Quantitative read-across for predicting toxicity and environmental fate related properties of organic compounds**

R Kühne, G Schüürmann, RU Ebert
Helmholtz Centre for Environmental Research - UFZ, LEIPZIG, Germany

Read-across provides predictions of compound properties through interpolation from known values of structurally similar substances. As such, it does not rely on molecular descriptors and their regression relationship to some target property, but on an approach to define structural similarity. Because chemical similarity itself cannot uniquely be defined, it requires reference to a concept and an associated operational procedure. To this end, we employ the methodology of atom-centered fragments (ACFs) that has recently been proven useful as tool to rank, in a predictive manner, the reliability of QSAR applications.[1]

The ACF method decomposes molecules into structural fragments consisting of a central atom and bonding neighbours. An ACF is then defined through the atom type and the number and type of bonding neighbours and associated bond types. Each non-hydrogen atom serves as central atom, while both non-hydrogen atoms and hydrogens may be used as neighbour atoms to define a particular ACF. First-order ACFs take into account only the directly bonded neigh¬bour atoms, second-order ACFs consider all atoms up to path length two in each bonding direction, and higher-order ACFs are defined accordingly.

In the present communication, we show the application of this ACF approach for quantitative predictions of compound properties, thus yielding an approach complementary to traditional QSARs. Read-across models for predicting acute toxicity towards fish and daphnids, the bioconcentration factor, and several partition coefficients with relevance for the environmental fate are presented. They demonstrate the power of the ACF methodology to identify property-relevant structural analogues. With regard to REACH, the results suggest the ACF-based read-across methodology as general non-animal approach for predicting aquatic toxicity, and thus to support the reduction and replacement of animal testing for chemical safety assessment.

Financial support by the European Commission through the project OSIRIS (Contract No. 037017) is gratefully acknowledged.

**PE01-4**

**Growth inhibition of 20 selected antibiotics and evaluation of non-testing support tools in environmental risk assessments**

L Andersson[1], T Backhaus[2], H Blanck[2], M Stenberg[1]
[1]Umeå University, UMEÅ, Sweden
[2]Department of Plant and Environmental Sciences, University of Gothenburg, GOTHENBURG, Sweden

Pharmaceuticals have been detected in sewage treatment plant effluents, in surface-, sea-, ground-, and drinking water. Concerns have thereby been raised regarding the fate and effect of pharmaceuticals in the environment. In this project antibiotics, including antimycotics and antivirals, were investigated. Risks associated with antibiotics concern bacterial resistance as well as their toxic effects. From a data base of 97 antibiotics prescribed for human use, a training set of 20 antibiotics was carefully selected to represent the chemical variation of the target group. The toxic activity of the 20 antibiotics was measured in a bacterial growth inhibition assay. Five of the tested substances showed a rather high activity with EC50 values below 1µM. Seven antibiotics showed very low, or no activity with EC50 values above 150 µM. The remaining eight tested substances had a rather even distribution of EC50 values from 3 to 90 µM. Classical univariate and multivariate QSAR approaches covering all compounds of the training set showed to fail. Hence, the dataset with 97 antibiotics was split into four groups using hierarchical cluster analysis aiming to develop cluster specific models. The clustering was based on the compounds variation in calculated chemical descriptors and the groups were separated largely based on molecular size and hydrophobicity of the substances. QSARs based on partial least squares projections to latent structures (PLS) were created and five non-tested antibiotics were suggested with potential toxic effect based on structural similarities with the most potent of the training set. Derived data was in addition compared with data provided by the risk assessment initiative in Swedish FASS and by data estimated using ECOOSAR. Initial comparisons indicated some incoherence between available ERA tools and the toxic potentials of the drugs as determined in this study.

**PE01-5**

**Biocides in paints in urban areas: modelling an underestimated source of environmental contamination**

S Coutu[1], C Rota[1], DA Barry[1], N Chèvre[2], L Rossi[1]
[1]EPFL, LAUSANNE, Switzerland
[2]Unil, LAUSANNE, Switzerland

Biocide contamination of receiving waters is generally linked with agriculture. However, recent studies have shown that urban contributions should be also considered. One of the suspected biocide sources in the urban environment is building paint. Biocides like diuron, irgarol, terbutryn, carbendazim, etc., are conventionally used in paint to control fungi, algae, bacteria and other microorganisms that can colonize building façades.
The problem of biocides in urban areas is closely linked to meteorological conditions and in particular to rain events. As a consequence, it is important to understand how rainwater collects and transports biocides from façades and how these biocides are transported in sewer systems to receiving waters. In this study, we present a conceptual model describing façade leaching and couple it with a Wind Driven Rain model and a classical hydrological model to compute the contribution of a city to the biocide load from building paint.
For the entire city of Lausanne (Switzerland, 200'000 inhabitants), a global production of 2200 kg/year of terbutryn leached by rain was estimated considering local building characteristics and meteorological information. The leaching model fitted well the peak in concentration measured at the bottom of the wall at the initial stage of the rain event. However, concentrations measured in an urban river in the watershed leads to the conclusion that most of this leachate does not reach directly receiving waters, but is infiltrated into soil or reaches the sewers after some delays in drainage pipes.
Release of biocides from façade leaching in the environment is systematic during rain event. It is of greater importance to estimate the dynamic of biocides during rain events and to compare these values with dedicated time varying environmental quality criteria.

**PE01-6**

**Treatment of volatile substances in the Activated Sludge Respiration Inhibition Test (OECD 209)**

E Scholten, H Schwarz
BASF SE, LUDWIGSHAFEN, Germany

Background and goals
The OECD 209 test is used to assess toxic effects of chemicals towards microorganisms in sewage treatment plants. In the revised guideline from 2010 volatile substances are for the first time explicitly addressed: i) the volatility of the substance should be known, ii) >80% of the substance has to remain in the reaction mixture, iii) a modified experimental set-up is needed for volatile substances but not sufficiently defined.
The goals of this work were i) to predict if substance volatility is an issue (i. e. the >80% target is missed), ii) to suggest experimental modifications for these cases, iii) to deduce an approach to recalculate ECX-values from old studies with volatile substances in which evaporation losses had been disregarded.
Approach
The Henry's law constant H of a substance was used as measure of its volatility.
Evaporation losses L of substances with different H-values were measured in a sludge-free set-up according to OECD 209. L-values after 30 and 180 min of exposure were plotted as a function of H, curve-fitting was performed and critical values Hcrit resulting in losses L of 20% were calculated.
The scientific literature was screened for possible modifications of OECD 209 for volatile substances resulting in reduced evaporation losses.
The L=f(H)-functions determined and mathematical description of air-stripping as first order-process were used to deduce an approach to recalculate ECX-values from old studies with volatile substances.
Results and discussion
i) L=f(H)-plots obtained showed the characteristics of saturation curves. Nonlinear fitting was performed with Monod-type equations.
ii) Critical values Hcrit of 0.6 and 4.8 (Pa m3)/mol were determined for 180 and 30 min of exposure under the test conditions. If H of a substance exceeds these values modifications of the set-up are required.
iii) The following modifications are options to reduce evaporation losses:
- Reduction of exposure time to 30 min or further
- Reduction of aeration rate
- Reduction of stirrer speed
- Reduction of incubation temperature
iv) The following steps for mathematical ECX-correction are suggested:
- Determination of H for test substance
- Calculation of L with L=f(H)-function
- Calculation of substance concentrations at the end of exposure c(t) from initial concentrations c(0)
- Calculation of the linear means clin from c(0) and c(t) using first order-kinetics
- Recalculation of ECX-values using the clin-values as corrected substance concentrations.

## PE02 - PBPK modelling in ecological risk assessment

**PE02-1**

**PBPK models in risk assessment - principles and application**

AJ Stevens, P Edwards, P Thorbek
Syngenta, BERKSHIRE, United Kingdom

Regulatory agencies within Pharma have embraced advances in PBPK modelling and incorporated them into regulatory requirements, approval pathways and regulatory decisions. Within the Ag Chem industry risk assessments are predominantly conducted on the basis of dose-response assessment and the application of generic uncertainty factors. The use of chemical-specific adjustment factors through the use of PBPK modelling would enable the risk assessor to consider and incorporate data on the mechanism of action together with toxicokinetics and toxicodynamics to enable more realistic human and mammalian risk assessments to be carried out. PBPK models are part of a continuum of increasingly data-informed approaches ranging from the default based on external dose to more biologically mechanism based dose response models. The physiologically based pharmacokinetic (PBPK) model is a compartmental model, but differs from classical pharmacokinetic models in that the compartments represent actual tissue and organ spaces and their volumes are the physical volumes of those organs and tissues. This talk will use examples to explain what studies are used to generate toxicokinetic data on which PBPK models can be based and how they can be validated through simulation and comparison with in vivo data and utilised to scale across species to indicate actual safety margins ready for the application of appropriate chemical specific safety factors.

**PE02-2**

**Developments in blood sampling and chemical analysis for PBTK modelling**

CS Laver, ST Brookes
Charles River, TRANENT, United Kingdom

Analysis of biological samples has undergone an evolution in the last 20 years leading to huge advances in the type and sensitivity of measurements that are now possible.
Developments in sampling, extraction, separation and detection techniques have moved the analytical aspects of studies from the peripheral to the mainstream. Developments such as DBS, UPLC, nano-LC and LC-MS/MS have combined to allow detection levels only dreamed about just a few years ago.

**PE02-3**

**Generic approach for developing PBTK models for different species**

W Schmitt
Bayer CropScience, MONHEIM, Germany

Physiologically based toxicokinetik (PBTK) modeling is more and more recognised as an appropriate tool for refinements of risk assessments which enables extrapolation to different exposure routes and patterns as well as extrapolation between different species. However, it is still a bit stigmatised as being too demanding in effort and data requiremtns and also too complex to be used in a regulatory environment. Efforts for developing and applying PBTK models can significantly be reduced by using a generic model structure and employing quantitative property-property relationships for estimating a large fraction of the chemical specific model parameters.
Methods for estimating steady state tissue:plasma partition coefficients and permeabilites of organic chemicals from their physicochemical poperties are discussed. For the such calculated partition coefficients a comparison to experimentally determined values shows a good agreement. Parameterising a generic PBTK model with the estimated parameter values together with in-vitro determined clearance values in many cases leads to results that compare well with in-vivo toxicokinetic data. Remaining discrepancies can often be resolved by limited refinements or inclusion of additional processes not considered in the generic structure, as e.g. active membane transport processes.
The above mentioned workflow demonstrated to work well and efficiently for developing PBTK models for several pesticides and examples of this will be shown. The such derived models are largely based on prior information independent of results from a particular toxicokinetic experiment. Thus they can be seen as predictive models which are only verified with and not fitted to oberved data and are thus well suited for being used in extrapolations to un-investigated scenarios by respective knowledge guided re-parameterisation.

**PE02-4**

**Application of physiologically based toxicokinetic (PBTK) modelling in bird and wild mammal risk assessment**

J Edwards, P Thorbek, A Stevens, P Chapman
Syngenta, BRACKNELL, United Kingdom

The current risk assessment paradigm for birds and mammals estimates risk as the ratio between toxicity and exposure using as inputs effects from an instantaneous gavage dose (acute) or the dietary toxicity over several days or weeks (chronic) with a single day or multiple repeats of a daily exposure, respectively. The acute risk assessment does not take account of toxicokinetic (TK) processes such as absorption and elimination or any associated behavioural effects limiting further exposure (avoidance). One option to refine risk is to explore the rates of absorption and elimination and behavioural responses through PBTK modelling, optionally in combination with dynamic process in fate and dissipation in the environment. The use of PBTK modelling is recommended as a refinement option by the European Food Safety Authority in their Birds and Mammals Guidance document (EFSA Journal 2009). A condition of PBTK modelling is that toxicity is the result of systemic exposure and is reversible as the systemic dose declines. The toxicokinetics may be evaluated by blood sampling and analysis following oral gavage dosing. Analytical approaches like liquid chromatography and mass spectroscopy (LCMS) allows very small blood volumes to be used with satisfactory limits of determination. Model simulations show that the systemic dose is sensitive to feeding and absorption rates, the avoidance threshold and elimination rate. The combination of feeding and absorption rates can lead to very different and counter intuitive outcomes for risk assessments. For acutely toxic seed treatments, high feeding and slow absorption rates present high risk, while high absorption rates do not and allow animals to regulate their feeding rate to below a harmful systemic dose by avoidance. Furthermore, applications of PBTK modelling may compare the contribution to the systemic dose made by oral, dermal and inhalation exposure and evaluate the risks from food chain bioaccumulation. The acceptability of PBTK models in regulatory risk assessment will depend on good validation of the PBTK models. This may be achieved by analysis of blood concentration in dietary studies. Examples of different scenarios for all these applications will be explored in this presentation together with the conditions and assumptions for PBTK modelling.

**PE02-5**

**Bridging insight from toxicokinetics and foraging ecology: case studies of acute risk assessment for insectivorous birds**

G Ochoa-Acuna
DuPont Crop Protection, NEWARK, United States of America

The recently enacted EFSA guidance for risk assessment of birds and mammals (EFSA Journal 2009; 7(12):1438) explicitly mentions consideration of toxicokinetics for conducting higher tier risk assessments of acute exposure. In the case of risks from acute exposure to compounds that have high rates of elimination (ke); dietary intake (feeding rate per minute, FPM of contaminated food items) may be too slow to approach the internal exposures that result from single, bolus administration by gavage of the pesticide as performed during testing. In 2005 the EFSA PPR laid out a basic framework for considering ADME processes during higher tier evaluations (EFSA Journal 2005; 240:1-21). As laid out, the approach rests on estimating two main inputs: FPM and ke. The opinion derived an estimate of FPM from a very limited number of studies and proposed a rather cumbersome approach for estimating ke. I have collected information from field and experimental studies to validate assumptions about FPM that may be used in these assessments. Data from small passerines demonstrate that birds precisely control the rate and timing of food consumption during the day to balance the need to secure adequate reserves for surviving during the night, and avoiding excess body mass during the day to facilitate take off and reduce predation risk. Field and laboratory studies have consistently reported that birds feed preferentially in the early morning and before dusk, with over 80% of mass gain occurring before noon. In addition, insectivorous birds experimentally forced to increase food intake through exposure to low temperatures and forced flying, showed an increase in meal size, but did not reduce time between feeding bouts (11-12 min). This demonstrates that birds are constrained by a digestive bottleneck, where feeding bouts are dictated by a fixed stomach and gizzard capacity. The increased food ingestion that occurs during periods of increased demand happens as a result of feeding over a larger proportion of available light hours. I also demonstrate, through nonlinear equation modeling, that ke should preferentially be derived from hen metabolism studies rather than as proposed, from the long-term NOEL and acute oral LOEL in the same species. The approach will be demonstrated with case studies using different birds and pesticides.

**PE02-6**

**Measurement of pesticide intake rates and avoidance thresholds for small mammals**

HM Thompson[1], PJ Edwards[2]
[1]Fera, YORK, United Kingdom
[2]Syngenta Crop Protection, BRACKNELL, United Kingdom

Behaviour e.g. food avoidance, can influence risk by preventing body burdens from exceeding harmful thresholds and is a measurable response that may be included in PBPK models. Standard avoidance tests only measure the response of wildlife to treated food items over a fixed period, e.g. how much does an animal consume over a 4 hr period compared with untreated food. Far more information can be generated from studies if the response of the animal to treated food is monitored continuously over the exposure period. Such data can be used to measure not just the intake rate but also the avoidance threshold and recovery period. The objective of this work was to develop a laboratory based method which could be used with small mammals to determine the highest ingestion rate of different pesticide active ingredients and formulations in food that may be tolerated and to determine if avoidance influenced the response. Two species of small mammal were used, the laboratory rat (Rattus norvegicus) and the woodmouse (Apodemus sylvaticus). The laboratory rat was chosen as LD50 data are routinely available and the wood mouse was chosen as a focal species of the small mammal likely to feed on treated seeds. Specific measures included an avoidance response time (feeding time before animals stop feeding) and the avoidance threshold (AVT) expressed as both the dose ingested and dose rate to the point at which feeding stopped. Dietary concentrations were prepared as a block made from ground diet and a binding agent into which the pesticide was incorporated. As data were required on the uptake of the treated diet over time, a remote method of monitoring uptake was used by videoing the output from a balance on which the diet was placed on the first day of exposure to treated food. Food consumption was measured to estimate the ingested dose and the avoidance threshold (AVT). The time from when individuals started to feed to when they first avoided food (avoidance response time) was determined with reference to controls.

## RA01 - (Non-)Extractability and bioavailability of organic chemicals in relation to analytical and regulatory issues

**RA01-1**

**Unified model for sorption, sequestration and degradation in soils and sediments**

SAJ Trapp[1], PM Mayer[2], AR Rein[1]
[1]Technical University of Denmark, KGS. LYNGBY, Denmark
[2]University of Aarhus, ROSKILDE, Denmark

The objective of this study is to combine ad/desorption models for organic compounds with the growth and degradation kinetics of microbes in a mathematical simulation model. The goal is to interpret and predict observed effects, such as increasing persistence with time, decreasing degradation rates with concentration, and effects of amendments on sorption and degradation. A second objective is the mathematical definition of the terms "persistence", "bioavailability"and "bioaccessibility".

A numerical model was set up that combines ad/desorption, microbial metabolism and the formation of non-extractable residues (NER). It contains the compartments non-aqueous phase liquids or solids (N), dissolved compound (D), adsorbed (A) and sequestered (S) compound, bacterial mass (X) and biotic as well as abiotic NER. The exchange between these compartments is expressed by rates. Bacterial growth follows Monod kinetics minus decay (maintenance) rate, degradation is due to bacterial maintenance or growth. The evolving non-linear differential equations are solved numerically. The model is formulated in activity notation and implemented in Matlab. Comparison to the analytical Best equation gave (for suitable scenarios) full agreement, which is a verification of the model structure, mathematics and implementation of the numerical model. Validation by comparison to experimental studies is underway (see Rein et al., this session).

The unified model allows the simulation of sorption, sequestration, bacterial growth and degradation processes simultaneously and coupled together. By this, we hope to get a better understanding of aging and persistence in soil and of the formation of bound residues (better: non-extractable residues), but the goal is also the optimization of amendments, such as DOC, compost or charcoal.

Acknowledgement - The authors thank the European Commission for funding by the FP 7 grant No. 245226 MAGICPAH"'Molecular Approaches and MetaGenomic Investigations for optimizing Clean-up of PAH contaminated sites, and the Research School of Environmental Chemistry, Microbiology and Toxicology (RECETO) for funding the project PUB - Prediction of persistence of soil pollutants under various conditions of bioavailability.

**RA01-2**

**Microbial contribution to the bound residue formation in soils**

E Kaestner, K Karolina, A Miltner
Helmholtz-Centre for Environmental Research - -UFZ, LEIPZIG, Germany

During degradation of organic pollutants in soil, a significant amount of the carbon remaining in soil is transformed to so-called bound or non-extractable residues. These residues can only be detected by use of isotope labeled compounds and are considered to consist of the parent compound or metabolites sorbed to the soil matrix. However, biomolecules such as fatty acids and amino acids were also found in the residue fraction indicating that C from the pollutant has been assimilated by microbial biomass. In order to estimate the extent of biogenic residue formation after incorporation of the carbon into microbial biomass, we investigated the fate of microbial biomass in soil using 13C-labeled bacteria. Even after one year of incubation, the remaining C was about equally distributed between microbial biomass different from E. coli and non-living soil organic matter. Hence, the latter fraction contributes to the 'bound residue' formation from pollutants in soil. The significant contribution of biogenic residue formation was confirmed for the microbial degradation of TNT, PAH´s, some pesticides and pharmaceuticals.

**Covalent binding of sulfonamide antimicrobials to organic matter and soil: the role of oxidative enzymes and metal oxides**

A Gulkowska[1], B Thalmann[1], J Hollender[2], M Krauss[3]
[1]Eawag / ETH Zurich, DÜBENDORF, Switzerland
[2]Eawag, DÜBENDORF, Switzerland
[3]Helmholtz Centre for Environmental Research, LEIPZIG, Germany

Rapid formation of nonextractable resiudes (NERs) of sulfonamides in soils indicates that covalent bonding is initially the dominant process of sulfonamide dissipation. As electrophilic quinone groups of organic matter, which are sufficiently reactive to undergo nucleophilic attack by sulfonamides are probably not stable for longer periods, we hypothesize that a continuous formation of these quinones by oxidative enzymes or Mn/Fe oxides is a prerequisite for NER formation. Understanding the nature and stability of the formed bonds is essential for an appropriate environmental risk assessment for these veterinary antimicrobials. Therefore, we studied the NER formation mechanisms of the radio-labelled sulfonamide sulfamethazine (SMZ) and the stronger nucleophile para-ethoxyaniline (EXA) with natural Leonardite humic acid (LHA) in solution and agricultural soil samples after selective removal or addition of oxidants. Additionally, we tested the stability of the obtained NERs against desorption and pressurized liquid extraction. Studies using dissolved LHA show that 35% of the sorbed SMZ could be desorbed in single solute SMZ system and 45% in the competition experiment with EXA. Strong covalent bonding of SMZ occurs in the presence of laccase in both single solute and competition experiment. In the control soil samples, 60% of SMZ formed NER in the presence of oxygen and only 30% under anaerobic conditions. Slower kinetics were shown for the reaction of SMZ when EXA was added few days prior to SMZ application. Addition of Mn oxide and model hydroquinones significantly decreased the extractability of SMZ and thus increased NER formation to > 85%. The study clearly shows that the action of oxidative enzymes or oxidants is involved in the formation of NER of sulfonamides in soils. But also quinone groups readily adding sulfonamides upon their entry in the soil are to certain extent present in soil organic matter which explains the NER fromation also under anaerobic conditions. After this initial phase the subsequent, slow NER formation phase might be either controlled by (i) the desorption of sulfonamides from the solid phase, which subsequently react with quinones continuously or (ii) a slow conversion of "unstable"covalent bonds into "stable"ones more resistant during the extraction procedure.

**RA01-4**

**Instantaneously decreased extractability of sulfadiazine in soil batch experiments**

T Müller[1], I Rosendahl[2], A Focks[1], J Siemens[2], J Klasmeier[1], M Matthies[1]
[1]University of Osnabrueck, OSNABRÜCK, Germany
[2]University of Bonn, BONN, Germany

Effects of antibiotics in soil on microbial end points, leaching potential and biodegradation depend on their (bio)availability, which is generally approximated by extraction methods with mild solvents. The sulfonamide antibiotic sulfadiazine (SDZ) shows typical 'aging' in soil, i.e. decreasing extractability over time. A sequential extraction method proved to be appropriate to investigate sequestration of SDZ in batch experiments (Förster et al., 2009, ES&T). Concentration dynamics over 200 days in these extracts could be described well by a conceptual kinetic model which included a reversible sequestration process as well as an irreversible sequestration resulting in 'non-extractable residues' (Zarfl et al., 2009, Chemosphere). The experimental results along with the model simulations indicated reduced extractability of SDZ already shortly after the start of incubation. We assumed this finding to be attributed to very fast processes, being possibly of relevance for risk assessment. Therefore, we performed a set of soil batch experiments focussing on the first 24 hours of incubation and tested two hypotheses: (i) manure leads to formation of micro-aggregates or provides additional sorption places, (ii) water content of the soil before spiking SDZ and/or manure influences the observed effect. SDZ was added with water or manure to soils of different water content (dry vs. wet). We used the proved sequential extraction method (1: $CaCl_2$, 2: methanol, 3: acetonitrile/water with microwave); analysis of SDZ was performed by LC-MS/MS.

Immediately after spiking SDZ solution to soil, extractability was reduced in all setups confirming processes on a time scale of minutes. No considerable differences in the initial SDZ distribution between the different experimental treatments were observed, so none of our two hypotheses could be confirmed. However, during the following 24 hours of incubation, sequestration proceeds further, reducing extractability of SDZ with $CaCl_2$ and methanol (EAS fraction), while simultaneously increasing extractability with the high-temperature method (RES fraction). Rate constants for a sequestration process from EAS into RES appeared fairly constant in all experiments. In contrast, rate constants for an additional sink process out of EAS were clearly lower in the water compared to the manure treatments, indicating a linkage to microbial activity.

**RA01-5**

**The influence of alternating dry-wet cycles on the water-extractability of aged 14C-pesticide residues in soils**

ND Jablonowski, A Linden, S Köppchen, D Goebbels, B Thiele, D Hofmann, P Burauel
Forschungszentrum Jülich GmbH, JÜLICH, Germany

Due to future climate predictions, an increase in droughts, followed by heavy rain events can be estimated. Soil drying and rewetting may have a considerable impact on an increased release of pesticides present in agricultural soils, representing a potential risk by pulse inputs to deeper soil layers or aquifers after rain events. Laboratory studies using soil containing environmentally long-term aged (9-17 years) 14C-labeled residues of the herbicide ethidimuron (ETD), methabenthiazuron (MBT) and the fungicide anilazine (ANI) showed a significant increase of 14C-activity in the water-extract after soil drying. The total water-extracted 14C-activity (the amount of residual 14C-activity in the sample equals 100%) accounted for 44% (ETD), 15% (MBT), and 20% (ANI) after 20 alternating dry-wet cycles. The amount of water-extracted 14C-activity from the constantly moistened soil remained significantly lower at 16% (ETD), 5% (MBT), and 6% (ANI) after 20 cycles, respectively. LC-MS/MS analyses of the raw water extracts of the dried

and rewetted soils revealed the parent compound ETD and MBT in detectable amounts (15.0 µg ETD kg-1 and 0.23 µg MBT kg-1 in total, in 0-10 cm ETD-soil / 0-30 cm MBT-soil), accounting for 1.83% and 0.01% of total applied parent compound per soil layer, respectively), but neither ANI nor the main ANI metabolite dihydroxy-anilazine could be detected. In comparison, the constantly moistened soil released significantly smaller amounts of residual pesticide fractions (2.76 µg ETD kg-1 in total, in 0-10 cm ETD-soil), accounting for 0.34% of total applied parent compound, respectively, but no MBT or ANI residues were detected).
For all soils the water-extracted dissolved organic carbon (DOC) was significantly higher in the previously dried soils, compared to the constantly moistened soils (ETD-soil: 10.8 vs 4.8%; MBT-soil: 8.4% vs 3.7%; ANI-soil: 9.8% vs 4.6% of total organic carbon in the soil). In case of the previously dried soils, the DOC content correlated with the measured 14C-activity in the aqueous liquids (ETD-soil: r=0.80; MBT-soil: r=0.81; ANI-soil: r=0.91).
The overall finding demonstrates a readily water-extractable pesticide residue fraction which can easily be removed from the soil, representing a potential risk for leaching. The data suggest that an increase in environmentally relevant dry-wet cycles may result in an increased remobilisation and release of aged pesticide residues in soils.

**RA01-6**
**Hidden hazard or safe sink? Approaches to consider non-extractable residues in the regulatory assessment of chemicals.**
A Höllrigl-Rosta, E Thumm
Federal Environment Agency (UBA), DESSAU-ROβLAU, Germany
Formation of non-extractable residues (NER) is regularly observed in studies on the fate of organic chemicals in soil. NER formation may be interpreted as a specific form of compound persistency ('hidden hazard') or as a detoxification step ('safe sink'). Despite the considerable scientific progress made in analysing NER and identifying their binding types, these insights have not yet been utilised in regulatory risk assessment.
In a workshop held at the German Federal Environment Agency (UBA), it was agreed that three main types of NER should be considered in regulatory schemes: Fixation of substance molecules by physical entrapment in the soil matrix can be reversed under certain environmental conditions. Those 'Type 1' NER must be considered as a reservoir for remobilisation of a chemical over prolonged times. In contrast, formation of strong chemical bonds between substance molecules and soil matrix will produce 'Type 2' NER, which are unlikely to be released in their original structure under environmental conditions. Finally, NER can also be formed via incorporation of single labelled atoms or small fragments from the original substance into biomass. These 'biogenic' NER are no longer structurally related to the original substance. While the formation of Type 2 and biogenic NER can be considered a 'safe sink', Type 1 NER would constitute a 'hidden hazard'.
A generic extraction scheme was suggested for residue analysis in the standard studies on the fate of organic chemicals in soil. Specific methods are required to determine the amount of biogenic NER. Extraction with non-destructive methods allows concluding on the available residue fractions. To differentiate between Type 1 and Type 2 NERs, a set of destructive extraction methods differing in strength is available, which may be complemented with sophisticated spectroscopic techniques. Where no information on their nature is available, NER should in principle be assumed to belong to Type 1.
Formation of Type 1 NER will have different implications on the environmental risk and hazard assessment. In particular, their potential for substance remobilisation will significantly impact groundwater risk assessment and persistence assessment. Existing trigger values and decision criteria for NER formation were deemed inappropriate for addressing those concerns; hence, a need for developing new criteria was identified.

## RA02 - Aquatic and terrestrial mesocosm and field studies - Messages from complex systems to academia, regulators, and industry

**RA02-1**
**Nutrient masking of macroinvertebrate community responses to ternary mixtures of insecticides**
C Alexander[1], JM Culp[2], DJ Baird[2], AT Luis[3], AJ Cessna[2]
[1]University of New Brunswick, FREDERICTON, Canada
[2]National Water Research Institute (WSTD, Environment Canada), FREDERICTON, NB, Canada
[3]GeoBio Tec, University of Aveiro, AVEIRO, Portugal
To determine the effect and effectiveness of mixtures of three insecticides (chlorpyrifos, dimethoate and imidacloprid) in nutrient limited and enriched streams, benthos were field collected and exposed to nutrients and insecticides over a 3 week period using artificial streams in a 2 x 5 factorial design: two nutrient levels and five concentrations of the ternary insecticide mixture. The two nutrient levels were nutrient limited (oligotrophic) and nutrient amended (mesotrophic). Equivalent toxic unit doses were summed to create a ternary insecticide dose (e.g., 0.1 + 0.1 + 0.1 = 0.3 TU). The five concentrations of the ternary insecticide mixture were control groundwater, 0.3, 0.6, 0.9 and 1.2 TU. A key result was that the presence of moderate nutrients masked the effects of insecticide mixtures on a suite of macroinvertebrate community metrics, particularly at low toxic unit doses (< 0.6 TU) which are ubiquitous in the environment. Thus, nutrient status is likely an important modifying factor that is underrepresented in the toxicological literature and yet greatly contributes to the difficulty of assessing community level responses in real systems. Further study of nutrient masking in more complex pesticide mixtures is warranted.

**RA02-2**
**Detectability of fifeteen 12,000L outdoor control aquatic mesocosms over one year**
H Sanderson
Aarhus University, ROSKILDE, Denmark
Zooplankton abundance and species richness in 15 untreated 12,000 L outdoor micro/mesocosms (n = 15) were monitored over the course of 1 year to document the inherent variability and statistical detectability between replicates. Hence, the first aim of the paper is to document the normal operation ranges of abiotic and biotic parameters. The second aim is a calibration study of the cosms, statistical power analysis were applied to derive the statistically minimal detectable difference (MDD) between replicates with default values set at; alpha = 0.1 and beta = 0.2. Copepod abundance and species richness generally demonstrated the best detectability at 0.31 and 0.16, respectively, (n = 15); 0.59 and 0.33 (n = 3). Total zooplankton abundance and species richness had the lowest detectabilities at 0.19 and 0.14, respectively, (n = 15); 0.35 and 0.3 (n = 3). Rotifers, due to their opportunistic and rapid life traits, had the lowest single-species abundance detectabilities at 0.54 (n = 15); 0.8 (n = 3),whereas macroinvertebrate species richness had the lowest detectability at 0.43 (n = 15); 0.7 (n = 3) over 1 year. We recommend *a priori* calibration of the study design relative to relevant MDDs. Moreover, it is suggested to consider alternatives to statistical null hypothesis testing.

**RA02-3**
**Examples of the novel design of mesocosm studies for compounds with differing properties**
SA Seamus[1], G Weyman[2]
[1]Cambridge Environmental Assessments, CAMBRIDGE, United Kingdom
[2]Makhteshim Agan, THATCHAM, United Kingdom
A great deal of advance thought and planning is required for many substances before initiating a mesocosm study. Otherwise there is a risk of conducting a study that is of limited regulatory use. Here we will give advice and considerations for mesocosm studies with compounds of varying properties and with different use patterns. This will be illustrated using two example state-of-the-art mesocosm studies conducted in 2009. In one example the compound has a short aquatic half life and is toxic to invertebrates; in the other example the compound has a long aquatic half-life and is toxic to algae. One study required special consideration of the exposure profile in the static mesocosm system versus the reality of flowing water, and a novel design following the principles of E-Link was used. The other study required special consideration of the analytical method to prove correct dosing. Both novel designs had different challenges, and both were technically successful. The thought and planning required for these studies will be described and discussed; and other design (and cost) considerations will be mentioned. It is hoped that this presentation will advance mesocosm study design and offer advice to those considering a mesocosm study. Due to the increasing complexity of exposure calculation and risk assessment, mesocosm studies must also increase in their design complexity in order to stay relevant to the regulatory risk assessment. It will therefore be necessary for both laboratories and regulators to be open to novel designs which do not necessarily fit with recent standards for mesocosm assessment.

**RA02-4**
**Ecological impacts of time-variable exposure regimes of the fungicide Azoxystrobine on the zooplankton community of outdoor microcosms**
MI Zafar[1], DM Belgers[2], RP van Wijngaarden[2], GA Arts[2], IR Roessink[2], TCM Brock[2], PJ van den Brink[1]
[1]Wageningen University and Alterra Research Centre, WAGENINGEN, The Netherlands
[2]Alterra Research Centre, WAGENINGEN, The Netherlands
The risks of pesticides to aquatic ecosystems are often assessed by performing cosm experiments evaluating a particular exposure regime (e.g. 1 pulse Applikation), Not necessarily corresponding with the exposure part of risk assessment (e.g. multiple applications).This mismatch is one of the biggest challenges in contemporary ecological risk assessment. The aim of the present study is to compare the effects of a chronic exposure with the effects of a peak exposure and a multiple peak scenario with an identical Area Under the Curve. For this, microcosms (water volume approx. 1270 L) were established using sediment of fine clay having communities typical of macrophyte-dominated freshwater ecosystems. Azoxysrobine is a systemic and strobilurin fungicide that currently is used on a number of agronomic and horticultural crops worldwide. Azoxystrobine was introduced into outdoor- microcosms using four different regimes; (1) A single Applikation of 31 µg a.s./L, ( 2) four applications of 16 µg a.s./L, with a time interval of 10 days and (3 and 4) a continuous exposure of 10 and 33 µg a.s./L for 42 days. Treatment levels of 1 and 4-pulse were based on 42d-Time Weighted Average (TWA) of 15 µg a.s./L which fall between the chronic 10 & 33 µg/L treatments.The Multivariate analyses of the zooplankton data set, reveals small variation in the pre-treatment period and large concentration-dependent differences with the control after start of the treatment. Effects are first observed for the single Applikation and the chronic 33 µg/L treatment followed by the 4 Applikation and 10 µg/L treatment. Taxa belonging to Copepoda (Nauplii, Cyclopoida and Calanoida) and Cladocera (Daphnia longispina) are the most responsive zooplankton species observed. Rotifera are indicated to have increased due to azoxystrobin exposure as a result of indirect effects. By the end of the experimental period, PRC shows the same effects magnitude for the pulsed treatment regimes, which are placed in between the chronic treatment regimes. This indicates that for long-term effects the TWA could be more important for most zooplankton species than the peak concentration.

**RA02-6**
**Comparison of arthropod community responses to an insecticidal active in different geographic regions**
FM Bakker[1], SA Aldershof[2]
[1]MITOX Consultants, AMSTERDAM, The Netherlands
[2]Bioresearch & Promotion, AMSTERDAM, The Netherlands
At present the hypothesis that arthropod communities in different geographical c.q. climatological regions respond differently to exposure to plant protection products has not been tested empirically.
In total ten GLP field studies at nine different locations with different cropping systems were used to test hypotheses on effects of geographical gradient on ecotoxicological response at population and community level. All trials had a randomized block design with 4 replicate plots (n=4) per treatment (active substance OP1 and a water-treated control). At the population level direct impact and duration of effects were calculated. Community level analysis was performed using Principal Response Curves analyses (PRC).
Arable arthropod communities were least similar (23-27% species overlap), and orchard communities were most similar (54-69% species overlap). Species overlap in the different cropping systems between and within geographical regions was similar. Species abundance (evenness) differed considerably in arable studies, but less so in orchard studies.
The two grassland studies had a similar distribution of initial effect classes, but the proportion of unaffected taxa was higher in the South. The arable studies, which tested higher application rates, had effect size distributions that were more skewed to the larger effect classes. In general all sites had a qualitatively similar response pattern. For the two apple studies involving relatively low application rates in North and South France, effect-class distributions were similar, with most taxa occurring in the 60-100% effect classes. Deviant results were obtained for two Spanish orchard

studies. More than 50% of the taxa was not affected after treatment in these trials.
PRC responses of North and South studies expressed by the first ordination axis were similar in all crop types. Both magnitude and duration of responses were similar, except the magnitude of the two studies performed in Spain were lower.
It is concluded that OP1 treatment effects were similar in studies performed in N- and S-Europe. Only a slight trend was observed that more and longer lasting adverse effects were detected in studies performed in the North.
In exception to the conclusion above, adverse OP1 treatment effects were clearly lower in orchard studies performed in Spain. Analysis of more Mediterranean studies is needed to examine whether this was related to geographical location or to other factors.

## RA04 - Environmental risk assessment and management of Plant Protection Products (PPPs) and biocides

**RA04-1**
**Assessing the mixture ecotoxicity of biocidal products- the challenge at product authorisation**
A Kehrer, D Frein, E Kretschmar, C Riedhammer, B Schwarz-Schulz
Umweltbundesamt, DESSAU-ROßLAU, Germany
Biocidal products are typically mixtures of one or more active substances as well as further ingredients. With the inclusion of the first substances in Annex I of the Biocidal Products Directive (BPD) 98/8/EC the authorisation of the corresponding biocidal products at national level is underway and European member states (MS) are facing mutual recognitions.
For the authorisation of biocidal products an extensive environmental risk assessment (ERA) is required in accordance with the BPD: not only every active substance in the product has to be subject of an environmental risk assessment, but also substances of concern, i.e., substances leading to classification of the product or having PBT, endocrine or CMR properties, have to be evaluated separately. In addition, estimation of mixture toxicity of the ingredients is required. The latter can be derived from ecotoxicological tests with the product itself, if a direct release of the product in the environment is possible. However, the product itself often does not represent the ecotoxicological relevant mixture since leaching and other paths of exposure will change the composition of the mixture. In that case, the ecologically relevant mixture, e.g. leachate water, has to be tested.
It is well accepted that mixtures of substances usually elicit a different toxicity than the isolated substances itself and additive effects up to synergistic effects are possible. Tests with the product or the ecologically relevant mixture therefore provide a meaningful method to demonstrate the degree of mixture toxicity by the joint action of the active substance(s) and further components of the product.
The German Federal Environment Agency is responsible for the environmental risk assessment of substances within the review programme of the BPD as well as for national product authorisation and proposes a tiered approach for the assessment of biocidal products based on the expected exposure pathways which also considers synergistic effects. The aim of the approach presented is to assess the mixture ecotoxicity of products and, where relevant, of ecologically relevant mixtures, and at the same time relieve the data requirements for the applicants as well as additional animal experiments.
The presentation gives an overview over the existing concepts for the assessment of mixture toxicty as well as on the proposed approach for product authorisation.

**RA04-2**
**Challenges to determine persistence of plant protection products in the PBT and vPvB classification for the new EU regulation 1107/2009**
J Dr. Hassink, K Dr. Szegedi, B Dr. Gottesbüren
BASF SE, LIMBURGERHOF, Germany
The new regulation for plant protection products (PPPs) 1107/2009 foresees regulation hazard based POP , PBT and vPvB cut -off criteria. The persistence (P) in the environment as a substances intrinsic cut-off criterion is utilized in conjunction with bioaccumulation (B), environmental toxicity (T) and long-range environmental transport. Considerable challenges are associated with the practical interpretation of persistence (P) as a hazard based cut-off criterion for the data rich cases of pesticides which may result in unjustified P classifications.
The vast amount of available information for pesticides in different environmental media and under different boundary conditions (laboratory and field conditions) allows a detailed and differentiated assessment of the behaviour. Detailed process based models in combination with predefined environmental scenarios (both agreed and established on EU level) and fate parameters obtained from low and higher tier studies are part of the pesticide regulation. These approaches allow to quantify with a significant level of certainty the persistence of pesticides within environmental compartments and the transfer and transport processes between them.
Approaches to determine pesticide fate parameters in different compartments are outlined and the exposure assessment for environment are presented with link to the P-classification.
Different proposals from academia, regulators and industry to address the P classification are compared with the results of the exposure assessments for pesticides in the EU.
Examples are provided that a hazard based assessment can lead to false identification of a potential concern whereas appropriate scientific based risk assessment shows an acceptable risk.

**RA04-3**
**Regulation 1107/2009/EC and upcoming challenges for exposure assessment of PPP - Harmonisation or national modelling approaches?**
E Erlacher, M Wang
Rifcon GmbH, HEIDELBERG, Germany
In the new European Pesticide Regulation 1107/2009/EC which will replace the existing EU Directive 91/414/EC in 2011, the harmonisation of risk-minimizing measures for the protection of aquatic organisms in the Member States is considered as important task. However, in many EU countries different models are currently used for the calculation of predicted environmental concentrations (PEC) in surface water and sediment and also the considered risk mitigation measures, such as spray drift reducing nozzles or buffer zones, differ between countries due to different geographical, climatic or agricultural conditions. This makes risk evaluations rather time-consuming for both the notifiers and the evaluating authorities, in particular concerning mutual recognitions of approvals. In the present study we compare EU and current country specific exposure modelling approaches and mitigation measures in order to evaluate if and to which extent harmonisation of exposure assessments in the EU is feasible.
The environmental exposure in surface water of 19 active substances was evaluated systematically according to EU and country specific modelling approaches. Calculations were conducted following EU requirements (FOCUS models) and country specific models for the UK, Germany and the Netherlands.
In the present analysis we show that EU and country specific models differ considerably in basic model assumptions, complexity and relevant parameters selected. Additionally, an important characteristic of the country-specific models is the prioritisation of specific entry pathways of pesticides (spray drift, drainage and runoff ) over substance specific properties. The acceptance of available risk mitigation methods differs significantly in each of the investigated Member States. The comparison with the EU modelling procedure shows that the national models do not necessarily comprise worst-case calculations. This fact particularly became apparent by comparing the PEC calculated following German modelling recommendations with the outcome of FOCUS calculations.
The results of this study highlight the differences of national exposure assessments for the protection of aquatic organisms. In spite of the possibilities of risk reduction, it is doubtful if any of these measures can be harmonised e.g. set as a standard all over Europe or at least in the countries of one zone according to the zonal approach of the new regulation 1107/2009/EC.

**RA04-4**
**Improving definition and selection of focal species used in risk assessment**
C Andrade, F Chiron, R Julliard
Museum National d'Histoire Naturelle, PARIS, France
Risk assessment investigates the potential impact induced by active ingredients on non-target organisms. In the higher tier of this assessment, focal species are chosen among a pool of real species likely to be exposed to treatment. According to Guidance Document, risk assessment must focus on occurrence, dominance, ecological and biological parameters of focal species, but it doesn't mention how to take into account each parameter in a single definition of focal species. Species occurrence within a given habitat is often used as the main criteria. However, it doesn't reflect the specificity of a species to a targeted habitat because very frequent species may also occur in many other types of habitat. In this presentation, we combined occurrence of species within a given crop (i.e. fidelity) with species specificity to identify focal species using the Indicator Value (IndVal) method and data from the French Breeding Bird Survey. We calculate the specificity and the fidelity of 94 common bird species, counted on 3 000 sampling points located in arable lands covering all French regions. The IndVal of a species increases with both its occurrence and its relative abundance in crops. Thus, top ranked species with a high indicator value are both frequent and abundant in selected fields compared to other types of habitats. Because the more frequent species are often generalist, frequent in a wide range of habitats, IndVal method enables to remove down generalist species and to take up specialist species into the ranking. Then, knowledge on their biology and ecology (diet, feeding layer...) contribute to select those that are more representative for birds exposure. Although the concept of specificity has a strong ecological meaning, it is largely overlooked in eco-toxicological risk assessment. Because specialists species occupy narrow ecological niche, they are good indicators of various environmental pressures and seem more vulnerable to environmental changes than generalists. Integrating specificity in the definition of focal species is a new emphasis in the area of ecological risk assessment and is likely to integrate species characteristics like geographical distribution, biological and ecological traits that make it dependent to this habitat. We propose to unify focal species definition by using the IndVal method. It could be extensively used at several scales and could contribute to the current issue on risk assessment using trait-based approach.

**RA04-5**
**Defining soil ecological exposure scenarios for pesticide risk assessment in the EU: an ecoregion approach**
FA Sousa[1], J Römbke[2], OM Schulz[3], C Gardi[4], J Filser[5], E Capri[6], R Luttik[7], K Nienstedt[3], A Schaeffer[8]
[1]IMAR-CMA, COIMBRA, Portugal

[4]JRC, ISPRA, Italy
[5]Universität Bremen, BREMEN, Germany
[6]Università Cattolica del Sacro Cuore, PIAZENZA, Italy
[7]RIVM, BILTHOVEN, The Netherlands
[8]RWTH Aachen Univesity, AACHEN, Germany
The current terrestrial risk assessment of pesticides is performed assuming a common exposure scenario for the entire EU based on the total concentration in the top 5 cm of soil. Aiming at modelling ecotoxicologically relevant concentrations in soil (ERCsoil), an alternative to this single exposure scenario is needed. Ecologically relevant scenarios should take into account the biogeographical differences within the EU in terms of soil, climate and the vertical distribution of soil organism communities. Here we present the progress achieved by EFSA on the development of an EU-27 Ecoregion map and associated exposure scenarios.
To test this approach, a compilation of biogeographical information on selected key soil fauna groups representing different morphological and ecological characteristics influencing exposure was performed. Data on presence of earthworms, enchytraeids, collembolans and isopods were collected from the literature for three model countries covering a maximum biogeographical gradient in Europe: Finland, Germany and Portugal.
Results obtained proved that the concept works. Ecoregion maps were produced for earthworms and enchytraeids and revealed marked differences between countries. For isopods, models revealed a dominance of litter dwellers in all countries, showing no differentiation. For collembolans, the lower resolution scale of some explanatory variables, allied to a bias in data towards forest sites, did not allow a discrimination between countries.
Based on the distribution maps for earthworms and enchytraeids, depth profile maps where to model ERC could be constructed. The results pointed out that for most of the situations in these three countries, the "worst case"soil depth profile for short-term risk assessment would be litter (if present) or 0 to 1 cm depth instead of the currently used 0 to 5 cm depth. This occurs since a large area in these countries is dominated either by epigeic species or by species that feed on litter (e.g., anecic earthworms). For other life-forms or for long term exposure, other depth profiles may represent the realistic worst case situation. For refined risk assessments, the geographical variation in depth profiles, crop and soil management information, as well as data about the ecology of soil organisms (e.g. different dominance distribution of soil communities) could be considered. Provided that information from other countries is available, the approach could be extended to the entire EU territory.

**RA04-6**
**When the active substance/PPP does not fit the legislation**
BS Iversen

CBC EUROPE Ltd, NOVA MILANESE, Italy
Directive 91/414/EEC, Regulation 1107/2009 and Directive 2009/128/EC are all related to the regulation of pesticides. Each of them intends to cover all different types of pesticides. CLP Regulation 1272/2008 concerns nearly all chemical substances and mixtures. It is by no means easy to make this type of generalised legislation, and it is by no means easy to cope with them if your active substance or plant protection product (PPP) does not fit the legislation. Authorities have to find ways to fit the legislation. Unfortunately this is not always done properly, resulting in non scientifically justified decisions, confusion and unnecessary effort to find solutions to problems. Equivalence assessment of technical materials is done according to Sanco/10597/2003. This guideline is not suitable for Straight Chain Lepidopteran Pheromones (SCLPs). Today (Nov. 2010) nearly two years after the SCLPs were included in Annex I there is still only a draft version of a proposed guideline. The industry is therefore left in the dark when estimating future market activities and requirements. Pheromones are released in a very slow and controlled way by VP dispenser formulations, unfortunately more Member States apply R50/53 (R51/53) environmental classifications to these formulations applying the calculation method according to Directive 1999/45/EC. The only possible risk to the aquatic environment from dispenser products would be a systematic opening of the packaging, cutting hundreds of dispensers into pieces and then extract the content from the pieces and put it into the water, which is a totally unlikely happening. Applying the calculation method is therefore not only scientifically unjustified but is also contrary to the whole concept of classification and the real intentions behind the legislation. Here the guidance for testing toxicity to aquatic organisms does not fit dispenser products. Concerning National Action Plans in the framework of the sustainable use directive, the R50 classification has been mentioned as a possible parameter for decision making. An unjustified classification under one regulation would here penalise a PPP under another directive. Conclusion: it is needed that regulators and authorities adjust in advance (specific guidelines) legislation to cases for which the legislation does not fit, and if problems come up due to non-fit situations scientifically justified and not bureaucratically based decisions should prevail.

## RA05 - Integrated science: Key to risk assessment

**RA05-1**

**Assessing the environmental risks associated with contaminated sites: 'ERICA: Environmental Risk Index for a Chemical Assessment'**

E Boriani, D Baderna, M Lodi, E Benfenati
Mario Negri Research Institute, MILAN, Italy

A risk assessment strategy considering the impact of chemicals on the whole ecosystem has been developed in order to create a sound and useful method for quantifying and comparing global risks posed by the main different hazardous chemicals found in the environment. This index, called the Environmental Risk Index for a Chemical Assessment (ERICA), merges in a single number the environmental assessment, the human health risk assessment and the uncertainty caused by missing or unreliable data. ERICA uses a scoring system with parameters for the main characteristics of the pollutants. The main advantage is that it preserves a simple approach by condensing in this single value an analysis of the risk for the area under observation.
The availability and reliability of the data is an important part of the work done to build the index. Experimental and predictive data were compared to evaluate the reliability. Data was derived both from literature sources (experimental models mainly) or predictive models. ERICA can be considered a diagnostic and prognostic tool for environmental contaminants in critical and potentially dangerous sites, such as incinerators, landfills and industrial areas or in broader geographical areas. The application of the proposed integrated index provides a preliminary quantitative analysis of possible environmental alerts due to the presence of one or more pollutants in the investigated site.

**RA05-2**

**Integrated risk indices to assess water quality**

E Semenzin[1], L Grassi[1], J Rizzi[2], A Zabeo[1], P von der Ohe[3], S Gottardo[2], A Critto[2], A Marcomini[2]
[1]Venice Research Consortium, MARGHERA - VENICE, Italy
[2]Venice Research Consortium and Ca' Foscari University of Venice, VENICE, Italy
[3]UFZ, LEIPZIG, Germany

The European Water Framework Directive (WFD) 2000/60/CE prescribes a series of tasks for properly assessing and managing river basins with the ultimate aim of achieving a good ecological and chemical status of surface waters by the end of 2015. The Ecological Status (ES) of each water body has to be evaluated and classified by using biological Quality Elements (QE) as key parameters and physico-chemical, chemical as well as hydromorphological QE as supportive parameters. Moreover, the Chemical Status (CS) has to be evaluated by comparison of measured concentrations of priority substances in water, sediment and biota compartments with Environmental Quality Standards (EQS) set at EU-wide level.
The overall assessment asks for an approach able to integrate different types and sources of information in order to identify the stressors playing a major role in affecting the ecosystem and to guide future management actions.
In this context, one of the main objectives of the MODELKEY project was the development of an Integrated Risk Assessment (IRA) methodology implemented into a Decision Support System (DSS) guiding decision makers in assessing and managing river basins according to the WFD requirements (i.e. MODELKEY DSS). In particular, Integrated Risk Indices (IRI) based on Multi Criteria Decision Analysis (MCDA) methods and Weight of Evidence approaches (WoE) were developed and calculated in order to evaluate and classify the ES and CS at site-specific scale (i.e. sampling stations). The developed IRI implemented into a DSS module (i.e. IRI module) were applied to several river basins in Europe.
In this paper, after introducing the IRI module we will focus on main results obtained by its application to Elbe and Danube River Basins, in order to highlight difficulties which are usually encountered in assessing water quality and to suggest how to overcome them by means of integrated risk-based approaches and decision support tools.

**RA05-3**

**Standard and non-standard tests for environmental risk assessment of human pharmaceuticals**

M Ågerstrand[1], V Roos[1], M Breitholtz[2], C Rudén[1]
[1]Royal Institute of Technology (KTH), STOCKHOLM, Sweden
[2]Stockholm University, STOCKHOLM, Sweden

The presence of pharmaceuticals in the aquatic environment has gained increasing attention over the last years, and concerns have been raised over possible negative impact on aquatic organisms since pharmaceuticals are designed to interact specifically with biological processes already at low concentrations. Indeed, the synthetic estrogen ethinylestradiol causes skewed sex ratios and impaired reproduction in fish and frogs at environmentally relevant concentrations. Since the regulatory requirements for pharmaceutical efficacy and safety are relatively far-reaching, their pharmacological effect, mode-of-action, and potential side effects in humans are generally well described. However, currently available standard test methods for deriving regulatory ecotoxicity data are in many cases not sensitive enough to measure the specific (pharmacological) effects that are expected.
We have analysed the relative sensitivity of standard and non-standard ecotoxicity tests to identify pharmaceuticals of concern to non-target species in the aquatic environment. Our results show that test results exhibit considerable variation between standard and non-standard tests performed for one and the same substance. In many cases, non-standard tests employ more specific end-points, yielding increased sensitivity. An illustrative example is ethinylestradiol where a comparison of available data shows that non-standard endpoints are 100 to 200 000 more sensitive than standard endpoints. In other cases, standard tests were more sensitive. However, for most pharmaceutical substances very few ecotoxicity studies exist and a comparison could not be made.
We conclude that the lack of relevant, robust, and sufficiently sensitive test methods is a major deficiency in regulatory environmental risk assessment of pharmaceuticals. Appropriate test methods are fundamental for risk identification and thus a crucial part of the risk assessment process. As we see it, there are at least three potential ways forward to improve the situation: (1) To develop new standard tests, (2) To adjust existing standard tests i.e. supplementing them with additional endpoints, or (3) To increase the use of non-standard tests.

**RA05-4**

**Application of a weight of evidence Triad approach in assessing impacts of diffuse contamination at regional scale**

A Dagnino[1], L Avidano[1], S Fenoglio[1], E Gamalero[1], C Oliveri[1], S Sforzini[1], A Viarengo[1], T Forte[2], M Peleggi[2], C Ottavi[2]
[1]Università del Piemonte orientale "Amedeo Avogadro", ALESSANDRIA, Italy
[2]Istituto Superiore per la Protezione e la Ricerca Ambientale, ROME, Italy

Triad-based ecological risk assessment aims to estimate environmental impacts due to contamination, encompassing chemical, ecotoxicological and ecological data. In fact, measuring biological effects allows assessing impairments on biota at different levels of biological organization (i.e. molecule/cell, tissue/organism, population/community) and estimating environmental risk and biological vulnerability.
Goal of this study is to evaluate environmental risk and biological vulnerability at regional scale in soils from Campania, Italy, that, as known, are impacted by deposition of organics. Levels of metals and metalloids, PAHs, PCDD/F and PCBs have been determined in 48 superficial soil samples; a 3-tiered ecotoxicological and ecological investigation has been realized. Triad data have been integrated by an Expert Decision Support System (EDSS) into 3 indexes: Environmental Risk Index, EnvRI, Biological Vulnerability Index, BVI, Genotoxicity Index, GTI.
In some samples, chemical results have shown concentrations of contaminats above the Italian maximum permissible concentrations for residential use. Ecotoxicological endpoints at high level of biological organization (i.e. survival and reproduction) haven't shown dramatic alterations. High variations of both functional and structural community parameters among sites have been evident. Changes in sublethal biomarkers have underlined the presence of bioavailable contaminants able to induce a sublethal stress syndrome.
Data have been compared to control (CTR) (i.e. lab control and pristine ecological values), and reference conditions (REF) (i.e. unpolluted sites) with the EDSS. The obtained risk values show variations of EnvRI ranging from 0.11 to 0.58 and from 0.06 to 0.51 respectively. BVI levels indicate a sublethal stress in model organisms, with values ranging from 0.26 to 0.51. GTI values allow individuating cases where significant effects on DNA are evident, with values ranging from 0.00 to 0.65.
Risk levels in the Campania region don't evidentiate critical situations (EnvRI below 0.75 in all sites). The contamination seems related to a general environmental degradation rather than to significant inputs of PCDD/F and PBCs from atmospheric deposition. However, BVI and GTI indicate sublethal stress conditions in the majority of sampling sites, suggesting that biological systems are suffering and that a decrease of pollutants input is necessary to reduce the risk of biodiversity loss in the study area.

**RA05-5**

**Is ecotoxicogenomics useful in fulfilling the goals of environmental risk assessment?**

N Dom[1], M Penninck[1], A Filby[2], C Tyler[2], D Knapen[1], R Blust[1]
[1]University of Antwerp, ANTWERPEN, Belgium
[2]University of Exeter, EXETER, DEVON, United Kingdom

The development of experimental approaches which offer additional mechanistically relevant information is widely considered to be beneficial in environmental risk assessment. Toxicogenomics technologies are regarded as excellent tools for the investigation of the biological mode of action (MOA) of a chemical. However, the data gathered through transcriptomics analyses is not readily applicable in a regulatory framework. The hypothesis that similar chemical treatments are reflected by comparable gene transcription profiles opens up perspectives for the development of strategies to group chemicals according to their MOA; transcript fingerprinting). Gene transcription profiling can additionally assist in the unravelling of a chemical's toxic MOA.
In this particular study, the potential of transcriptomics is investigated in a cross-species setting using a group of structural analogues (chlorinated anilines; aniline, 4-chloroaniline, 3,5-dichloroaniline, 2,3,4-trichloroaniline). Although the toxicity of these group of polar narcotics is assumed to be similar, our previous study illustrated large interchemical and interspecies differences in toxicity. Knowledge on the mechanistic basis of toxicity is essential to understand why the different test species differ in their responses to the four structural analogues. These settings offer the perfect basis to investigate the potential added value of an across-species transcriptomics approach. Therefore, we aimed at evaluating whether the different toxic MOAs can be distinguished based on differential gene transcription data, and how transcriptomics data can give additional information that is essential to explain the interchemical and interspecies differences observed in the acute toxicity study. In a second part, the specific difficulties we encountered and the potential benefits of the application of transcriptomics in an environmental risk assessment context will be discussed in a broader perspective.
The results of this study illustrated that for simple structural analogues (chlorinated anilines) MOA data can not be extrapolated among different species (daphnia versus fish). It is obvious that additional biological information provided via transcriptomics studies is beneficial in a risk assessment context. It is however still too early to suggest one standardized procedure to be implemented in a risk assessment context e.g. under REACH.

**RA05-6**

**A review of methods for analysing standard data: is there a place for non-standard methods?**

CD Forfait, E Billoir, ML Delignette-Muller, S Charles
Université Lyon 1, VILLEURBANNE, France

Even if new types of bioassays and thus of data arrive on the ecotoxicology market, standard data and associated statistical analyses are still worth interesting, because they are still widely used within laboratory routine and regulatory context. In particular, several classical toxicity thresholds are established from standard procedures, carried out according to the OECD either to collect experimental data or to implement appropriate analyses. The No Observed Effect Concentration (NOEC) and the 50% Effective Concentration (EC50) are listed among the preferred in terms of environmental policy and risk assessment. Some years ago, an alternative, still non-standard, emerged: the No Effect Concentration (NEC).

Nevertheless, statistical analyses, classically recommended to deal with standard data [5], are far to be clear and easy to use, and call for careful thought. We propose to review standard statistical analyses that are classically performed on standard survival data to estimate NOEC and LCx, adding a non-standard NEC estimate method, and discussing pros and cons of these different methods. For each threshold type, several methods are compared. In case of NOEC, three hypothesis test methods are compared: the Jonckheere-Terpstra's test, the Cochran-Armitage's test if a monotone dose-response is expected, and else the Fisher's exact test with the Bonferroni-Holm correction. In case of LCx, three dose-response models are fitted in parallel: the log-logistic, the log-probit and the Weibull models. In case of NEC, we chose one threshold model with a three-phase linear stress function.

We illustrate our words with nine standard survival data sets from literature, all concerning the freshwater invertebrate Daphnia magna exposed to copper, zinc, cadmium, potassium dichromate, chlordane, ivermectine, oxolinic acid, streptomycin or sulfadiazine. For each threshold type, pros and cons are discussed, and the most appropriate method is emphasized. Such a review finally aims to warn regular users against a misuse of p-values, against the consequences of the prior choice of an arbitrary value (the x in LCx), or against the consequences of the choice of a particular model. Hence, we suggest to use [0 - LOEC] confidence intervals, possibly to use LCx values with a wittingly chosen x, or even better to use NEC-type toxicity thresholds, which combine all advantages and statistical properties to become reliable and relevant in the framework of environmental risk assessment.

## RA07 - Monitoring data and post-registration studies for PPPs: generation, compilation and use in the environmental risk assessment and management

**RA07-1**

**Birds & mammals: balanced decision-making is a social responsibility. Field effect studies & incident reporting provide the link to the real world. Example of OP insecticide chlorpyrifos.**

M Norman[1], G Weyman[2], MT Douglas[1], T Staedtler[3], C Wolf[4]
[1]Dow AgroSciences, ABINGDON, United Kingdom
[2]Makhteshim Agan, THATCHAM, United Kingdom
[3]Rifcon GmbH, HEIDELBERG, Germany
[4]Tier 3 Solutions, LEICHLINGEN, Germany

Over-precaution has a cost to society. In recent years, some active substances in EU have been heavily restricted due to lower-tier risk assessments for birds & mammals. Plant Protection Products (PPP's) are tools to enable efficient production of food, to feed a growing population. In this context, it is our responsibility to make balanced scientifically-robust decisions based on 'real risks' to decide if specific PPP's should be available to EU farmers. Chlorpyrifos is an OP insecticide, applied as a spray in many EU countries on a wide range of crops. 'Tier 1' assessments indicate potential high risk. A large program of field studies has been run: brassicas (Poland), pome fruit (Italy & Czech Rep.), grapevines (France) and citrus (Spain). These include acute and long-term studies on both birds & mammals. The results will be presented. There are two publications ([1] [2]). Overall, no effects of chlorpyrifos were seen. There are no reported poisoning incidents relating to registered spray uses (annual use around 2.7 million ha). The evidence indicates a low risk, enabling regulators to judge actual risk for this important insecticide. Overall it can be concluded that a holistic view of data from the lab and field is needed before judging unacceptability or acceptability of the risk. A holistic view of regulatory decisions is also needed as alternative pest control options (if there are any) may present a greater risk.

**RA07-2**

**A post-registration study in France investigating effects of an insecticide-seed treatment on the honeybees**

AO Alix
MAAPRAT, PARIS, France

The placing of Plant Protection Products (PPP) on the market requires, as mandatory and in accordance with Directive 91/414/EC and the updated related Regulation to come, an assessment of the risks posed by their uses in crop protection to the environment. This risk assessment usually rely worst case risk scenarios, in estimating exposure conditions and exposure levels that are safe to the group of organisms or ecosystem considered. The most refined risk assessments, even relying on up-to-date exposure measurements, ecotoxicological studies and field studies may not address all the uncertainties associated to the occurrence of exposure and effects in the field. In the case of honeybees and other pollinating insects, these uncertainties are related to the conditions for exposure that are the rule in the field (multi-exposure to PPP but also to other background chemicals and veterinary products), indirect effects of crop management techniques (management of field boundaries) and extrapolation of a risk assessment based on the honeybee to other pollinating insects. A post-registration survey has been performed in France, which investigates the effects of the exposure to maize fields grown from insecticide-coated seeds in apiaries. Practical aspects of this survey implementation will be presented, together with the advantages and limits of the approach, in comparison to dedicated field studies and monitoring approaches.

**RA07-3**

**Pesticide pollution monitoring in streams for the identification of appropriate risk mitigation measures**

R Ohliger[1], M Streloke[2], R Schulz[3]
[1]Institute of Environmental Sciences, LANDAU, Germany
[2]Federal Office of Consumer Protection and Food Safety, BRAUNSCHWEIG, Germany
[3]Institute for Environmental Sciences, LANDAU, Germany

Risk mitigation measures are becoming increasingly important especially as regulatory frameworks like the European Water Framework Directive or the EU-framework for sustainable use of pesticides require higher standards. Their effectiveness under field conditions are currently examined at specific stream catchments in intensive agriculture in Germany. At a first step stream catchments were monitored to detect pesticide pollution and to develop proposals for appropriate risk managment strategies.

The monitoring was carried out in 2009 at 10 sampling sites in an intensive field crop region in central Germany and at 9 sampling sites in a vineyard region in south-west Germany. Pesticide residues in the water and sediment phase were determined following heavy rainfall events. Moreover an ecological monitoring (macroinvertebrate community) and a landscape monitoring (water body and riparian buffer strip characterisitcs) was performed.

In the field crop region maximum permissible concentrations of insecticides (mainly alpha-cypermethrin, lambda-cyhalothrin, pirimicarb) and fungicides (epoxiconazole, spiroxamine, tebuconazole, fenpropimorph) were exceeded mainly in the sediment but also in the water phase. In the vineyard region, mainly fungicides (especially folpet, tebuconazole, azoxystrobin, fludioxonil) accounted for the pesticide pollution. The evaluation of macroinvertebrate data using the SPEAR-concept, showed that in both study areas water quality is predominantly "poor"or "bad"(field crop region: 7 sampling sites; vineyard region: 6 sampling sites).

In the field crop region the sampling sites with a higher pesticide pollution differed from less polluted sampling sites regarding riparian buffer strip width and vegetation, the number of erosion rills and neighbouring fields of presumed increased higher exposure potential. In the vineyard region, the concrete road network and associated erosion rills leading the runoff in the water body are regarded as main pesticide entry routes. Runoff samples exemplarily taken in erosion rills showed the same pesticide residues as samples from the stream but in higher concentrations.

The different patterns of pesticide pollution in the two study regions show that a differentiated approach for the identification of appropriate mititgation measures is required. At identified higher polluted stream sections appropriate measures are planned to be implemented and evaluated in a further monitoring phase.

**RA07-4**

**Pesticide and nutrient discharge from greenhouses in Norway: preliminary investigations 2007 and 2008**

R Roseth[1], R Holten[2]
[1]Bioforsk, AAS, Norway
[2]Norwegian Food Safety Authority, AAS, Norway

Preliminary investigations of pesticide and nutrient discharge from Norwegian greenhouses indicate that these effluents can influence water quality and biological diversity in downstream recipients.

During the autumn of 2007 a total of 29 water samples were grabbed in small streams and ditches downstream 9 greenhouses, mainly producing flowers. Pesticide residues were found in 90 % of the samples. A total of 18 different pesticides were detected; 9 fungicides, 5 herbicides and 4 insecticides. Six fungicides (cyprodinile, propiconazole, iprodione, azoxystrobin, prochloraz and vinclozolin) and 3 insecticides (pirimicarb, diazinon and chlorfenvinphos) were found in concentrations exceeding the Norwegian standard for environmental effects. The fungicides pyrimethanile, iprodione and imazalile were detected in concentrations higher than 1 µg/l. The grab samples that contained high concentrations of pesticides also contained high concentrations of nutrients typical for a greenhouse effluent (0.8 - 7.4 mg P/l and 6 - 42 mg N/l). Further investigations in 2008 included grab samples in the drainage system of 10 greenhouses, but also samples in streams and ditches downstream greenhouse plants. A total of 49 water samples were analysed for pesticides and nutrients. Pesticide residues were found in more than 90 % of the samples. A total of 25 different pesticides were detected; 11 fungicides, 7 herbicides, 6 insecticides and 1 growth regulator. Two fungicides (cyprodinile and imazalile) and four insecticides (pirimicarb, endosulfan, chlorfenvinphos and lambdacyhalotrine) were found in concentrations exceeding the Norwegian standard for environmental effects. The maximal nutrient concentration in drainage water was 30 mg P and 650 mg N/l.

The results confirm that greenhouse discharge may contain harmful concentrations of pesticides and nutrients. The results demonstrate a huge variation in effluent concentration as a function of production, operation, water handling system and water consume. The total discharge of pesticides and nutrients are expected to be efficiently reduced when including environmental aspects in planning, construction and operation of the greenhouses. Optimization of the water handling system (irrigation and drainage) is especially important.

**RA07-5**

**Pesticides in surface and groundwater - Italian monitoring data 2007-2008**

P Paris[1], S Bartolini[2], N Cerioli[2], T de Santis[2], D Esposito[2], E Pace[2], D Romoli[2], S Ursino[2]
[1]1The Institute for Environmental Protection and Research, ISPRA., ROME, Italy
[2]Institute for Environmental Protection and Research, ISPRA, ROME, Italy

ISPRA since 2003 carries out the national report on the presence of pesticides in surface and groundwater in order to provide on a regular basis information on the quality of waters in relation to the risk of these substances. The report is the result of a complex activity involving regions and regional environmental protection agencies (ARPAs) that perform surveys and transmit data to ISPRA, which coordinates the activities providing methodological documents, guidelines and evaluating data.

Pesticides are chemicals used to control weeds, insects and other pests in agricultural areas, and a variety of other land-use settings. In the European Union, from a regulatory point of view, we can distinguish substances used in plant protection products and biocides, which are used in various fields (disinfectants, wood preservatives, pesticides for nonagricultural use, antifouling, etc.). The use of these substances raises issues about possible adverse effects on humans health and the environment, because most of them are molecules generally hazardous to all living organisms.

During these years, the activities of planning made it possible to focus the survey on substances actually used and to identify priorities in relation to the potential risk. This activities provided the basis for harmonization of regional monitoring programs and at the same time, the realization of a national system for managing information on the topic.

The results of national monitoring of surface and groundwater held in the years 2007-2008, will be showed. We present the contamination level found, for comparison both with the limits fixed for drinking water, and for comparison with environmental quality standards defined in recent years by the EU and national legislation.

**RA07-6**

**Could sustainable use directive provide solutions for a better pesticide risk management?**

AV Marchis, EC Capri, GS Sacchettini, ED Durigon
OPERA Research Centre, BRUSSELS, Belgium

Introduction

In September 2009 the Council of the European Union adopted the so called pesticides package (PP). The PP includes the Directive 2009/128/EC (SUD). The objective of the SUD is to achieve a sustainable use of pesticides by implementing a plan for risk and use reduction. OPERA is a research centre of the Università Cattolica del Sacro Cuore (UCSC). It is an independent, not-for-profit scientific think tank, committed to the successful integration of agro-environmental measures within European legislation. Within this context OPERA reviews and advise in the implementation and measurement of risk reduction methodologies, which are crucial for the successful implementation of the SUD.
Activities
Several parallel activities have been implemented by OPERA to contribute to the success of the implementation of the SUD:
- Selecting the right risk indicators
- Developing mitigation measures
- Reforming the CAP
Results
Relating to the selection of the right risk indicators, OPERA has put forward a proposal of a possible pool of indicators to select from when elaborating the NAP. Risk Indicators are expected to help national regulatory bodies to assess trends in pesticide risk reduction and to judge the effectiveness of their programmes. The risk indicators issue is the subject of two OPERA publications. Regarding the example of field margins, the efficiency of such a solution to protect the environment and human health depends on multiple factors. It has emerged that the implementation needs to take into account and coordinate with other legal requirements to establish such buffer zones. OPERA has treated this subject in its publication "Multifunctional Landscapes".
Related to the CAP, agriculture has to be perceived as a strategic sector due to its multifunctional role for the society. We have created a participatory process to debate with stakeholders the most important bottlenecks for the future policy. This resulted in a series of documents, available on the OPERA website, to elaborate on the issues of concern as well as in a opinion paper submitted to the European Commission in the process of public consultation on the future of the CAP.

## RA08 - PBT substances

**RA08-1**
**Screening for PBT chemicals in the set of chemicals in commerce**
M Scheringer, S Strempel, K Hungerbühler
ETH Zürich, ZÜRICH, Switzerland
One important innovation of REACH, the new European chemicals legislation on the Registration, Evaluation, Authorization and restriction of chemicals, is that REACH includes a quantitative assessment of chemicals concerning their persistence, bioaccumulation potential, and toxicity (PBT assessment). Key questions for the PBT assessment under REACH are: how many PBT chemicals are there in total and what types of chemical structures will be present in this class? What are suitable approaches to identifying these chemicals? Here, we present a screening for PBT chemicals in a set of 100'000 chemical structures. We establish a PBT scoring system and, to apply this system to the set of chemicals, estimate the chemical property data needed using methods from the Estimation Programs Interface Suite [1]. To obtain PBT characteristics of these 100'000 chemicals, we defined a PBT scoring system. For each chemical, subscores for P, B and T were calculated and integrated into one overall score. Each subscore is the ratio of a chemical property value and the corresponding REACH threshold (a degradation half-life of 60 days, a BCF of 2000, and a NOEC of 0.01 mg/l). The subscores were added and their sum divided by three. A PBT chemical (all three thresholds exceeded) has three subscores of 1 and also a total score of 1. Using the PBT scores, we defined four hazard classes into which we binned all 100'000 chemicals. The class "PBT"contains chemicals with a score of 1, "nonPBT2"chemicals with two subscores equal to 1, "nonPBT1"chemicals with one subscore equal to 1, and "nonPBT0"chemicals with all three subscores below 1. The four classes contain 2919 (2.8%), 8194 (8.0%), 28019 (27%), and 63'673 (62%) chemicals for PBT, nonPBT2, nonPBT1, and nonPBT0, respectively. Many chemicals in the PBT class contain chlorine, bromine or fluorine, and also highly branched alkyl substituents and nitro groups are observed. To investigate the influence of uncertain chemical property data on the PBT scores, we varied first the half-lives, then the BCF values, and finally the toxicity data of all chemicals by a factor of two and re-calculated the PBT scores. This showed that the number of chemicals in the PBT class is most sensitive to changes in the BCF, followed by the biodegradation half-life, whereas the influence of the toxicity data is much weaker.

**RA08-2**
**Estimation of kinetic rate constants from water-sediment standard tests**
J Klasmeier, M Matthies
University Osnabrueck, OSNABRUECK, Germany
Data from water-sediment tests are often exploited by estimation DT50 and DT90 values for disappearance from water, sediment (where applicable) and total system and categorization the compounds according to the total amount of non-extractable residues (NER). However, there are at least five different processes that have to be separately considered: (i) transfer of the substance from water to sediment (back and forth), (ii) primary degradation in the water phase, (iii) primary degradation in (bulk) sediment, (iv) emergence of non-extractable residues (NER), and (v) mineralization to $^{14}CO_2$. We determined kinetic rate constants from data of various pesticides in water-sediment test systems that were made available by the German Federal Environmental Agency (UBA, Berlin). Data sets were fitted to a first order kinetic process model that separately considers the five processes mentioned above. A non-linear optimization algorithm (Levenberg-Marquardt) with least-square fit was used. Most of the data sets could be successfully fitted to the model with realistic rate constants for metabolization in sediment, increase in NER (decrease in extractability) and $CO_2$ evolution. These rate constants can be transformed to half-lives that allow for much more realistic assessment of persistence by avoiding misinterpretation of DT50 values as biodegradation half-lives in water.
In general, it turned out that biodegradation of parent compounds basically occurs in the sediment. Rate constants for degradation and mineralization in water were always estimated to be zero, unless the compound was prone to abiotic hydrolytic degradation. Thus, first-order rate constants for loss from water describe the diffusive transfer into sediment and should not be used to derive degradation half-lives. Instead, bulk degradation rate constants for sediment can be determined from the model fit. These degradation rate constants are often quite different from DT50 values for total system that were used as an assessment criterion for persistence in official documents. Another important factor is the phenomenon of non-extractable residues that occur for some of the compounds. Model simulations indicate that the process behind the observed decrease in extractability is kinetically determined and not or only very slowly reversible. This is manifested by the steady increase of NER fraction over time.

**RA08-3**
**Organic pollutants with long-range transport potential in oceans are persistent**
C Zarfl[1], M Scheringer[2], M Matthies[1]
[1]University of Osnabrück, OSNABRUECK, Germany
[2]Institute for Chemical- and Bioengineering, ETH Zurich, ZURICH, Switzerland
According to the Stockholm Convention on Persistent Organic Pollutants (POPs) [1] substances are prone to long-range transport with atmospheric currents if they are characterized by a half-life in air of more than two days. In addition, pollutant transport may also occur within the water compartment. An analogous half-life criterion is, however, not given. Therefore, we derived half-life criteria characterizing LRTP in water based on flow velocities of European rivers and ocean currents running into the Arctic Ocean. The well-established concept of characteristic travel distance (CTD) calculated by a multimedia model takes partitioning between environmental compartments and degradation behaviour into account [2] and was transferred to substances primarily transported within the water compartment. On a global scale, which is especially significant as far as an international chemical assessment is concerned, derived half-life criteria for LRTP in oceans are significantly smaller than current persistence criteria in water as defined by the Stockholm Convention and the European chemical legislation (REACH). Consequently, organic pollutants prone to LRTP in oceans are already registered as substances of very high concern by the persistence criterion. Simulations with the multimedia model ELPOS [3] of perfluorooctanesulfonic acid (PFOS) which is included in Annex B of the Stockholm Convention as a persistent organic pollutant show a higher CTD in water than in air. Nevertheless, simulation of the waterborne POP PFOS supports the LRTP and POV boundaries derived by Klasmeier et al. [4] with a well-established set of reference chemicals basically transported by atmospheric currents.

**RA08-4**
**Hexachlorobutadiene marine risk assessment for the North Sea and evaluation of secondary poisoning risks**
D van Wijk[1], SR Presow[1], AG Jones[2]
[1]Euro Chlor, BRUSSELS, Belgium
[2]Canadian Chlorine Chemistry Council, BURLINGTON, Canada
Hexachlorobutadiene (HCBD) is a chemical of historic interest, and was utilised in several processes by the chemical industry. Due to concerns about its persistence, bioaccumulation potential and toxicity, the use of HCBD in industrial applications in Europe has essentially ceased. It can also be generated as a by-product from some chemical syntheses. Emissions of the substance in Europe are currently extremely low, on the order of 140 kg/year to water (2008) (E-PRTR). Given that discussion of this substance is ongoing in various forums, it was decided to conduct a risk assessment of this substance. The risks for the marine environment were assessed according to the methodology laid down in the Guidance Documents of the EU Existing Substances Regulation 793/93. The risk is indicated by the ratio of the Predicted Exposure Concentrations (PEC) and the Predicted No-Effect Concentrations (PNEC) for the marine aquatic environment. For the North Sea risk assessment a PNECwater value of 130 ng/l and a PNECsed value of 24.4 µg/kg dw were derived. From the available monitoring data a $PEC_{water}$ of 6 and 12 ng/l and $PEC_{sed}$ of 1.1 and 4 µg/kg dw were derived for a typical and a worst case situation, respectively. As all PEC/PNEC ratios are well below one, overall the data are supportive of the conclusion that the levels of HCBD in the marine environment do not pose an unacceptable risk. As HCBD has PBT properties it is appropriate to also consider risks for secondary poisoning. The SETAC POP/PBT workshop (Integr Environ Assess Manag, October 2009) recommended that one method to assess this risk is the use of Critical Body Burden (CBB). CBB values could be derived from the available literature data, which allowed the determination of the risk to marine species from the measured exposure. With regards to the CBB calculation, it can be shown that the measured body burdens are seven orders of magnitude below the most sensitive calculated CBB. This represents a wide safety margin between actual and critical body burdens.

**RA08-5**
**Accumulation of persistent organic pollutants in the Mediterranean population of Catalonia**
M Gari, JO Grimalt
Institute of Environmental Assessment and Water Research (IDÆA-CSIC), BARCELONA, Spain
Persistent Organic Pollutants (POPs) are typically produced for agricultural and industrial applications, possessing notable toxicity potential and persistence, therefore representing a threat to human health and the environment itself. The most relevant POPs are the organochlorine (OC) pesticides β-HCH, 4,4'-DDT, its major metabolite 4,4'-DDE and HCB, PCBs and PBDEs. They are commonly encountered in humans, and blood serum analysis is the simplest method for assessing their body burden.
The present study reports the occurrence of these compounds in Catalonia, a Mediterranean country of 32,000 $km^2$ and 7.5 million inhabitans, with notable agricultural and industrial sectors. It is based on a public health survey conducted by the Government of Catalonia in 2002, that included a health exam and a blood testing for 919 people.
All studied individuals from the population of Catalonia show detectable levels in one or several organochlorine compounds (OCs, n=919), with a detection over 75% of the samples. Regarding PBDEs (n=310), the most abundant congener is BDE-209, with almost 60% of detection level. In general terms, all these OCs concentrations tend to be slightly higher than in many other previously studied populations, such as the U.S., some asian studies and the European populations from Germany and the U.K. The concentrations are however lower than in populations from economies in transition such as Romania and Slovakia, or from those that have a particularly high exposure to OC-related chemicals: a population from the Canary Islands and the Flix township in Catalonia itself. Regarding PBDEs, these concentrations also tend to be higher than european and asian studies, but lower than the U.S. population.
The concentration of OCs in the population of Catalonia increases with age. Regarding PBDEs, this age effect is not clearly observed. Sexual differences are also observed in the present study. The most notorious observation is a much higher concentration of several OCs in women, particularly HCB and β-HCH (both of them with statistically significant differences). In the

case of 4,4'-DDT, 4,4'-DDE and PCB-118, their concentrations are also higher in women. In contrast, men have moderately higher concentrations of PCB-138, PCB-153 and PCB-180. Finally, PBDEs do not show differences between sexes, although men tend to have slighly higher concentrations.

**RA08-6**

**Influence of physical-chemical properties on the transference of organochlorine compounds from serum to breast milk**

M Fort[1], JO Grimalt[1], J Ibarluzea[2], L Santa-Marina[2], J Sunyer[3]
[1]Institute for Environmental Assessment and Water Research, BARCELONA, Spain
[2]Subdirección de Salud Pública de Gipuzkoa, Dept. of health - Basque Government, SAN SEBASTIAN, Spain
[3]Centre for Research on Environmental Epidemiology, BARCELONA, Spain

Introduction and objectives. Human milk is lipid-rich and a good store of lipophilic pollutants such as organochlorine compounds (OCs). These pollutants are circulated throughout the body by the venous system and retained in breast milk due to their lipophilic properties. Studies addressing the influence of the specific physical-chemical properties of these pollutants on breast milk accumulation are needed. The present study is based on the analysis of a large number of pairs of colostrum and serum samples in which the concentrations of OCs have been determined. The resulting database is used to assess the dependence of breast milk retention on these properties.

Methodology. 361 paired colostrum and serum samples were analysed for HCB, four HCH isomers, DDT and its metabolites and 7 PCB congeners. For those compounds detected in at least 50% of samples in both cohorts, colostrum:serum concentration ratios were calculated using the ng/g lw values, and then compared with physical-chemical properties of the compounds, such as log Kow, log Koa and molecular weight.

Results and discussion. Concentrations of OCs in serum and colostrum were significantly correlated ($p<0.001$). The colostrum:serum ratios exhibit certain variability between subjects but a well defined compound dependent trends is observed, being PCB 180 and β-HCH the compounds with highest and lowest median ratios, respectively. This compound-dependence has been found to be related to the log Kow and molecular weight values. More lipophilic compounds and with heavier molecular weight were preferentially transferred to breast milk. The pesticides exhibited a clear trend with lipophilicity and PCBs seemed to be more influenced by their molecular weights. Colostrum lipid concentrations were 5-fold higher than serum, this difference in lipid content between both matrices seemed to be relevant for the distributions of these compounds and their transference from one fluid to the other.

Conclusions. The paired concentrations of OCs from colostrum and serum samples were significantly correlated. Calculation of colostrum:serum ratios for each individual compound showed that the more lipophilic and heavier OCs were those preferentially transferred from serum to breast milk during the first days of lactation. The different lipid contents of these two fluids were consistent with these observations.

## RA09 - Risk assessment in the marine environment and regulation

**RA09-1**

**Assessing the risk of chemicals in the marine environment: regulation and science issues**

MB Duchemin[1], PC Thomas[1], J Kohli[2], G Deviller[1], P Adrian[2]
[1]Consultancy for Environment and Human Toxicology and Risk Assessment, VAUX-MILIEUX, France
[2]CEHTRA, BRUSSELS, Belgium

The risk assessment of chemicals in marine ecosystems is becoming more and more a mandatory part of regulations for chemical management. The new European chemical legislation REACH will gradually produce a large amount of information on the hazardous properties, use and exposure of chemicals. Other environmental policy frameworks, in particular those where environmental quality standards are used to safeguard environmental quality, will benefit from this accelerated generation of information. On the other hand, marine species are mandatory for risk assessment under the OSPAR regulation without excluding freshwater data. Furthermore, each regulation is covering parts of marine waters from coastal to offshore waters while those waters can have deep environmental parameter differences (turbidity, salinity, ecological traits, etc.). The aim of this presentation is to describe briefly regulatory data requirements and related methodologies and to highlight scientific basis of hazard and exposure assessments in coastal waters and offshore waters. The second aim of this presentation is to stress gaps of knowledge for sound risk assessment in the marine environment. The third aim is to induce discussion about risk management at the boundaries of the regulations.

**RA09-2**

**Composing batteries of ecotoxicological tests to assess marine sediment quality**

R Baudo[1], M Faimali[2], F Onorati[3], D Pellegrini[3]
[1]CNR ISE, VERBANIA, Italy
[2]CNR ISMAR, GENOVA, Italy
[3]ISPRA, ROMA, Italy

In the frame of the activity of UNICHIM (Italian Organization for Standardization in Chemistry), a committee was established to evaluate the possibility of devising one or more batteries of ecotoxicological tests, in order to support monitoring programmes of the quality of sediment from marine coastal waters and transitional waters. The committee produced a 5 parts document, which is now proposed to the scientific community for a peer review.

The document provides not only practical examples of batteres of ecotoxicological tests suitable for the assessment of the quality of sediment from marine coastal waters and transitional waters, but in addition it suggests a way to compare different batteries, on the basis of their respective scientific and practical relevance.

The document addresses also the problem of combining the results of tests concurrently applied to the same sample, and indicates how to summarise those results on both a toxicity and a risk scale.

**RA09-3**

**A proposed minimal saltwater ecotoxicity data set that can be tiered based on risk assessment needs**

A Cafarella, C Ronald, P Shepherd
Smithers Viscient, WAREHAM, United States of America

There are no specific saltwater testing requirements in the major European environmental legislation regulating chemicals (REACH), pesticides (Directive 91/414/EEC or Regulation (EC) No 1107/2009) or pharmaceuticals (Directive 2001/83/EC). Due to the inherent physiological differences between freshwater and saltwater organisms it is logical to hypothesize that one of the groups of organisms will be more sensitive to a specific chemical than the other. Therefore, it is important to provide sound saltwater testing paradigms since marine organisms can be more sensitive than freshwater organisms. It is difficult to predict which chemical substance will be more toxic and simply applying safety factors can provide a false sense of security or can be over protective when not warranted. One basic paradigm is founded on developing a data set on a limited number of taxa that adequately protects the low end of the species sensitivity distribution as well as helps define the chemical response curve. The objective of this presentation is to demonstrate how the two marine species, the sheepshead minnow (Cyprinodon variegatus) and the mysid (Americamysis bahia) when combined with a basic freshwater data set can provide one example on how to develop a tiered saltwater testing paradigm that takes advantage of the principles of species sensitivity distributions, dose-response relationships for a given species-chemical combination and the principle that some species will be inherently sensitive to most chemicals. Based on exposure assessments and associated toxicological concerns additional marine species will be recommended to systematically expand the data base. Due to time limitations marine algae and plants, and marine benthic dwelling organisms will not be discussed.

**RA09-4**

**Assessing the acute effects of an Hazardous and Noxious Substance (aniline) on the common prawn Palaemon serratus: swimming behaviour and biomarkers**

LG Luis[1], LG Guilhermino[2]
[1]CIIMAR, PORTO, Portugal
[2]ICBAS/CIIMAR, PORTO, Portugal

In the last decades, the concern about the spills of oils and Hazardous and Noxious Substances (HNS) in the sea has been increasing due to both short and long-term ecological and economic impacts. Aniline a very toxic compound and one of the HNS transported at high volumes by ship. Despite the studies that have been done on the toxicity of this HNS, a considerable lack of knowledge still exists on its effects on marine invertebrates. Therefore, the objective of this study was to assess the effects of aniline on the common prawn (Palaemon serratus), a species with a wide distribution in the Atlantic (from Denmark to Mauritanea), where it can be found in estuaries, coastal areas and offshore waters until a depth of about 40m. It is an important prey of several fish, some of them with high economic interest. In a first bioassay to calculate 50% lethal concentrations (LC50), animals were exposed for 96h to several concentrations of aniline, in semi-static conditions with appropriate medium renewal, in a photoperiod (16h light: 8 h dark) and temperature ($20\pm1^{o}C$) controlled room. In a second bioassay, animals were exposed in similar conditions to high but sub-lethal concentrations to assess effects on behaviour and several biomarkers, namely, the activity of the enzymes acetylcholinesterase, lactate dehydrogenase, isocitrate dehydrogenase, several anti-oxidant enzymes and glutathione S-transferase, and lipid peroxidation levels. The 96h-LC50 of aniline to P. serratus was 18.3 mg/l (95% CL: 11.2-29.2 mg/l). The HNS was able to decrease the swimming velocity of the common prawn and caused significant alterations in several biomarkers. These results indicate that aniline spills may have a direct acute impact in exposed populations of this species since intoxicated animals may have a decreased capability of avoiding predators and capture preys, as well as reduced capabilities of performing physiological functions determinant for their survival and performance. This study was done in the scope of the project RAMOCS funded by the Portuguese Foundation for the Science and Technology (FCT) and FEDER funds (ERA-AMPERA/0001/2007, EU ERA-NET AMPERA ERAC-CT2005-016165) and was also supported by FCT (European Social Fund and national funds from the "Ministério para a Ciência, Tecnologia e Ensino Superior"- MCTES) though a research grant to Luis Luis (SFRH/BI//51043/2010).

**RA09-5**

**Altered timing of metamorphosis in early life stages of Antarctic krill (Euphausia superba) exposed to p,p'-DDE**

AH Poulsen[1], S Kawaguchi[2], J Kukkonen[3], M Leppänen[3], SM Bengtson Nash[4]
[1]The University of Queensland, BRISBANE, Australia
[2]Australian Antarctic Division (AAD), KINGSTON, TASMANIA, Australia
[3]University of Eastern Finland, JOENSUU CAMPUS, Finland
[4]Griffith University, BRISBANE, Australia

p,p'-DDE is a persistent organic pollutant (POP) found to accumulate in wild populations of a key Southern Ocean species, Antarctic krill. Despite the ecological significance of Antarctic krill, there is little ecotoxicological data available for environmental risk assessment of the species. This study evaluated the effects of p,p'-DDE aqueous exposure (1 - 20 µg/L, nominal) on the earliest larval stages of Antarctic krill (N1, N2, MN and C1). In tests A to C, larvae were exposed to p,p'-DDE for 1, 3 and 9 days post hatch (dph) in order to target A) developmental progress of N1, B) metamorphosis to N2 and C) metamorphosis to MN. In test D, larvae were exposed to p,p'-DDE for 5 dph and monitored in clean seawater until 21 dph (to reach the C1 stage). Developmental timing was accelerated in p,p'-DDE exposed larvae from N1 to MN; i.e. the proportions of A) N1 with premature tail spines, B) fully metamorphosed N2 and C) fully metamorphosed MN were significantly ($P < 0.05$) higher in p,p'-DDE treatments compared to solvent controls. Some p,p'-DDE exposed N2 larvae were further found to have unusually protruding tail ends. The results of test D support acceleration of larval development in p,p'-DDE exposed larvae until the MN stage, whereas metamorphosis to C1 was impeded. No mortality was observed in tests A to C. In test D, mortality was however, increased in the p,p'-DDE treatments from the onset of metamorphosis to MN and continued to increase throughout the MN stage until 18 dph. These findings indicate that the MN stage is more vulnerable to toxicant induced stress than the preceding larval stages. The observation of aggravated effects in Antarctic krill larvae long after exposure has ended further demonstrates the significance of delayed effects of contaminant exposure. The observed delayed responses could be the first in a cascade of indirect effects caused by the initial stimulatory stress. All developmental endpoints were significantly induced from the lowest p,p'-DDE exposure concentration tested (1 µg/L) resulting in an internal lowest observed effect concentration (ILOEC) of 10.1 µmol/kg wet weight (1 dph). The obtained effective body residue for Antarctic krill larvae is comparable to those known to cause developmental effects in temperate species and one order of magnitude lower than the residue leading to sublethal narcosis in larval krill, strongly highlighting the importance of developmental endpoints for environmental risk assessment.

**RA09-6**

**Tools for assessing the contaminant situation in the Baltic Sea - reproduction disorders in amphipods**

M Löf[1], B Sundelin[1], M Reutgard[1], G Akerman[1], V Jermakovs[2], I Purina[2], M Balode[2]
[1]Stockholm University, STOCKHOLM, Sweden

[2]Latvian Institute of Aquatic Ecology, RIGA, Latvia
Assessing the effects of contaminants on ecosystem health requires not only measuring the concentrations of contaminants in the environment or biota, but also to study their effects on ecologically relevant biomarkers in species naturally occurring in the study area. It is crucial to rely on robust biomarkers in risk assessment and marine monitoring, i.e. ones that respond solely to the contaminant imposed stress being investigated but not to environmental fluctuations in abiotic or biotic conditions. This study is part of the BONUS project "BEAST"which aims to identify a broad range of such biomarkers on various species in the Baltic Sea.
In the marine environment organisms are exposed to a mixture of contaminants with different modes of toxicity and potential interactions. It is therefore fundamental to investigate the total toxicity of sediments and understand their effects on marine organisms in order to give recommendations. Reproduction disorders in amphipods measures as embryo malformations is a sensitive and early warning bioindicator to contaminant exposure. Effects of potential co-occurring stressors as oxygen deficiency, food availability and temperature have been thoroughly examined and found not to affect frequencies of embryo malformations.
In this study for the first time we directly link embryo malformations with a large span of contaminants (trace metals, PAHs, PCBs, DDT, PBDE) analysed in both whole crustaceans and sediment. Amphipods were sampled in contamination gradients in the Bothnian Bay, the Gulf of Riga and the Gulf of Gdansk, in 14 sites in total. Chemical analyses are under progress but the six contaminated sites are expected to display a broad contamination profile. The hypothesis is that some contaminants might have a larger influence on the embryo malformations than others. Suitable multivariate analysis will be performed to quantify their specific influence on the response variable.
The results show that there is a clear increase in levels of embryo malformations in contaminated sites for both the Bothnian Bay amphipods and the gammarids from the Gulf of Riga and the Gulf of Gdansk. This study shows that amphipods of different species can be used as tools to measure contaminant stress and that background levels of embryo malformations do not differ between species. Thus this method can be used in various parts of the Baltic Sea for risk assessment and to determine the ecosystem health in specific areas.

## RA10 - Risk assessment of chemical mixtures: how can we crack the nut?

**RA10-1**
**Risk assessment of POP mixture: the case study of the Arctic**
M Vighi
University of Milano Bicocca, MILAN, Italy
Persistent organic pollutants (POPs) are global contaminants, capable to reach remote areas, and particularly cold regions, trough long range transport patterns. Therefore, detectable concentrations may be measured in sites very far from direct emissions, such as polar areas (Arctic, Antarctica) and high mountains. Several groups of chemicals have physical chemical characteristics that allow reaching remote areas. Some of them are already regulated under the Stockholm Convention (the so-called Dirty Dozen); many others are still in use in relatively large amounts. Therefore remote areas are exposed to complex mixtures of POPs.
In this Case Study an exercise is described to assess and quantify the composition of a "realistic"mixture, likely to occur in a remote area like the Arctic. The hypothesis on which the exercise is based is that in remote areas, far from emission sites, where only long range transport may occur, only environmental and geographical characteristics may affect environmental concentrations. It may be assumed that, due too many characteristics (relatively uniform cold temperature, absence of dry-land, etc.), the Polar Arctic Circle is a relatively homogeneous area. Therefore, POPs concentrations may be assumed as relatively homogeneous and data from different literature sources may be considered as comparable.
A simple trophic chain has been considered. Literature data on POP concentration have been collected for water, fish (polar cod, Boreogadus saida), ringed seal (Pusa hispida), and polar bear (Ursus maritimus) as one of the most representative Arctic top predators. Three levels of mixture risk were taken into account: (1) fish exposed to mixture in sea-water; (2) seals eating fish; (3) bears eating seals.
The results show that the risk for fish exposed to the low concentrations present in water is negligible. However, the transfer in the trophic chain may produce significant risk for predators. Considering that most POPs are known to be endocrine disrupting chemicals, damages to reproduction and development are likely to occur.

**RA10-2**
**Quantifying in vitro bioassays data: Mathematical methods to estimate bio-equivalents introduce a high degree of uncertainty**
M Wagner, M Behr, A Magdeburg, J Oehlmann
Goethe University Frankfurt am Main, FRANKFURT AM MAIN, Germany
Quantification is a key issue when interpreting in vitro bioassay data. Commonly, so-called bio-equivalents (e.g. estradiol or dioxin equivalents) are used to quantify the endocrine potential of complex human or environmental samples in relation to a well-characterized, prototypical reference compound. However, there is no generally accepted data analysis strategy for estimating bio-equivalents from this type of studies.
Therefore, within this presentation we will (I) review mathematical procedures for the derivation of bio-equivalents from the body of literature, (II) critically assess the accuracy of the most common models to predict bio-equivalents, and (III) propose measures to reduce uncertainty in the calculation of bio-equivalents.
By scrutinizing the literature covering the period of 1990 to 2010 we compiled a data base of more than 200 publications that report bio-equivalents. From the published data we extracted three main data analysis strategies to calculate bio-equivalents. These models are based on linear or nonlinear interpolation, and the comparison of $EC_X$ values.
To assess and compare the models' accuracy, we employed simulated data sets in different scenarios. This theoretical calculations indicate that the linear and the $EC_X$ model considerably misestimate bio-equivalents in most of the scenarios (-20 to 2,000% deviation). Compared to that, the less employed nonlinear model predicts correct bio-equivalents in all cases. Following the actual estimation, bio-equivalents are commonly transformed to a defined reference volume or mass of the sample (e.g. one kilogram sediment). Since this is achieved by linear extrapolation additional inaccuracy is generated.
Taken together, our evaluation indicates that data analysis by itself introduces a considerable degree of uncertainty in the derived bio-equivalents. To increase accuracy in bio-equivalent estimation, we will present strategies to improve data analysis as well as experimental design of in vitro bioassays.

**RA10-3**
**Interactions and their impact on the applicability of concentration addition for environmentally realistic mixtures**
T Backhaus
University of Gothenburg, GOTHENBURG, Sweden
Regulatory guidelines make heavy use of Concentration Addition (CA) as a tool for predicting and assessing the toxicity of chemical mixtures. CA assumes that the compounds in a mixture do not interact with each other, neither in their toxicokinetic nor in their toxicodynamic phase. However, several of those interactions are described in the scientific literature for almost all major groups of environmental chemicals. These result in essentially synergistic or antagonistic mixture toxicities, i.e. higher, respectively lower mixture toxicities than expected by CA. With a view on the regulatory risk assessment of chemical mixtures, it is hence important to quantify the range of expectable synergisms, respectively antagonisms.
I discuss the quantitative consequences of interactions for the predictive power of CA using two published studies on the hazards and risks of environmentally realistic mixtures. One case study concerns the human health effects of a mixture of anti-androgens, the other the ecotoxicity of a pesticide mixture. Based on a series of simulation studies in which interactions were gradually assumed to occur in the mixtures, I outline the limiting cases (worst case situations) as well as the fundamental relationship between expectable deviations from CA and number of mixture components, mixture ratio and number of interacting substances in the mixture.

**RA10-4**
**Working with the regulator to determine key risk-driving compounds**
M Archer[1], A Thomas[1], L Thomas[2], L Croasdell[2], R Stahl Jr.[3], T Bingman[3], A Guiseppi-Elie[3], D Fletcher[3]
[1]CH2M HILL, LONDON, United Kingdom
[2]RSK, MANCHESTER, United Kingdom
[3]DuPont, WILMINGTON, DE, United States of America
Risk assessment is currently underway for a contaminated site in Northern Ireland with a wide variety of compounds of potential concern (COPCs). The risk assessment follows the UK CLR11 framework for management of contaminated sites, leading the site from investigation to remediation and ensuring a "suitable for intended use"outcome. The experience we aim to share is the process of determining key risk-driving compounds for the site while involving the regulator throughout the entire decision making process.
The current phase of works is focussed on assessing the risks to human health and the water environment from multiple COPCs. With this large number of substances detected over several years of investigation at a relatively large site, one of the initial challenges has been clearly evaluating and then communicating the relevance of these compounds so as to focus on the key issues and potential risks.
Rather than deriving generic assessment criteria (GAC) for a large number of COPCs under multiple land uses, the approach adopted was to first identify and focus the assessment on the key risk-driving compounds. Compounds were evaluated based on receptor (humans, aquatic and wildlife species) and with regard to toxicity, physical and chemical properties, spatial distribution, frequency of detection and magnitude of exceedence of adopted target concentrations. Compounds detected in association with each pollutant linkage were placed into chemical groups and, by working through the evaluation procedures, one or two key risk driving compounds were identified within each group.
Ultimately, of the compounds identified originally, approximately 30 were identified as likely to be key risk-drivers and were carried further into the risk evaluation process. Efforts to derive GAC will then focus on this manageable list of key compounds.
Discussions with the regulatory agency have provided the basis for streamlining the assessment. The regulator was engaged during the early stages of developing the compound evaluation approach and provided with the opportunity to review documentation progressively. Transparency in communication and decision making is key and ensures continued alignment as the risk assessment progresses in a timely manner.

**RA10-5**
**Risk assessment of single substances and mixtures of micropollutants in the Belgian coastal waters**
AN Ghekiere[1], F Verdonck[1], E Monteyne[2], K Wille[3], AN Goffin[4], C Janssen[5]
[1]ARCHE, GHENT, Belgium
[2]Management Unit of the North Sea Mathematical Models, OSTEND, Belgium
[3]Laboratory of Chemical Analysis, Ghent University, MERELBEKE, Belgium
[4]Flanders Marine Institute, OSTEND, Belgium
[5]Ghent University, Laboratory of Environmental Toxicology and Aquatic Ecology, GHENT, Belgium
Assessing mixture toxicity is a complex issue and therefore not implemented in the current EU legislations. It is practically not feasible to assess experimental mixture toxicity with all combinations of chemicals present on the market and in the environment. In the existing INRAM (Integrated Risk Assessment and Monitoring of micropollutants in the Belgian coastal zone, 2006-2010) project, one of the aims is to study the possibilities of assessing mixture toxicity through an integrated risk assessment approach. More than 100 micropollutants (e.g. pesticides, endocrine disruptors, pharmaceuticals) were analyzed in the Belgian coastal harbors. A database was subsequently developed summarizing all toxicity and ecotoxicity parameters of these chemicals (e.g. PNEC, DNEL, BCF, TDI). Both a single substance risk assessment (PEC/PNEC) approach and a mixture toxicity approach based concentration-addition were performed for the analyzed substances.
The main conclusions of this study are: the lack of basic data to support both the exposure and effects assessment, the need to quantify uncertainty, better justification of environmental quality standards, field evidence for the occurrence of mixture toxicity and development of tools to assess the trade-off between conservatism and uncertainty. A pragmatic approach is needed to determine the level of conservatism in exposure and hazard assessment for the implementation of mixture rules in the current EU legislations without accumulating conservatism.

**RA10-6**
**On the use of mixture toxicity assessment in REACH and the Water Framework Directive**
K Syberg[1], TS Jensen[2], N Cedergreen[3], J Rank[1]
[1]Roskilde University, ROSKILDE, Denmark
[2]Aarhus University, National Environmental Research Institute, AARHUS, Denmark
[3]University of copenhagen, Faculty of Life Science, Department of Agricultural Sc, COPENHAGEN, Denmark
This review seeks to connect scientific theory of mixture toxicity to its implementation within

different regulatory frameworks both within Europe and the US. The aim is to demonstrate how mixture toxicity assessment can be more thoroughly integrated into the European chemical regulations, REACH and the Water Framework Directive (WFD), using the experiences gained through other regulatory frameworks. The paper consists of 1) an examination of the scientific underpinnings of the range of methods used to assess the joint action of chemicals; 2) how such methods have been used in different regulatory frameworks; and 3) how such methods could be applied within REACH and WFD. It is concluded that REACH and WFD include mixture toxicity assessment to a very limited extent at the moment. However, it is shown that it is both scientifically feasible and regulatory practicable to integrate a more holistic mixture toxicity approach in both legislations. This will require that a limited number of chemicals are used in each mixture toxicity scenario. Those with individual PEC/PNEC > 0.1 is recommended to be included. Furthermore the construction of a database that includes data on chemicals in the European environment could help determine the relevant chemicals for each mixture toxicity assessments.

## RA11 - Risk assessment of chemicals within REACH integrating alternative methods and non testing strategies

**RA11-1**

**Threshold of toxicological concern assessment: investigation of possible improvments by means of in silico methods**

M Pavan[1], S Barlow[2], A Bassan[1], A Boobis[3], E Fioravanzo[1], AP Worth[4], C Yang[5]
[1]S_IN Soluzioni Informatiche, VICENZA, Italy
[2]Consultant, BRIGHTON, United Kingdom

[5]Altamira, COLUMBUS, United States of America

The Threshold of Toxicological Concern (TTC) approach is a screening tool based on the principle of establishing human exposure threshold values for chemicals, below which no significant risk to human health is expected. According to this approach, a safe level of exposure can be identified for many chemicals based on their chemical structure and the known toxicity of chemicals which share similar structural characteristics. This generic approach was first developed for the endpoint of cancer by the US FDA in the 1980s and adopted in 1995 as the 'Threshold of Regulation' for food contact materials. Since then, the TTC concept has evolved over the years to take into account extensive analysis of available data on mainly the oral toxicity of substances for toxicological endpoints other than cancer. Using a structure-based decision tree, the Cramer classification scheme, together with information on human exposure, the TTC approach has been applied, mainly in the food area. It has been used to evaluate flavouring substances, food contact materials, genotoxic impurities in pharmaceuticals and for the risk assessment of other chemicals. In 2010 the European Food Safety Authority (EFSA) funded the present research project aimed at investigating how the applicability of the TTC approach can be improved by incorporating physicochemical data and toxicity data generated by non-testing methods. The Cramer classification scheme, which is used to classify chemicals according to their structural chracacteristics, was analyzed to assess whether an alternative classification based on molecular descriptors might be useful in refining or replacing the original Cramer classes.In the current study the two major TTC datasets were retrieved, verified and analyzed, the Carcinogenic Potency Database (CPDB), including additional carcinogens based on Kroes et al , provides TD50 values, and the Munro dataset covering non-cancer toxicological endpoints. The chemical space covered by the two datasets was characterised using several molecular descriptors and explored by means of a variety of chemoinformatics techniques. The chemical space of the datasets was also compared against the wider universe of chemicals, as represented by the Distributed Structure-Searchable Toxicity (DSSTox) Database developed by the U.S. Environmental Protection Agency (EPA) as a reference. Finally, a refinement of the Cramer structural classes was proposed which identify structural subclasses.

Implementation of REACH requires demonstration of the safe manufacture and use of chemicals. REACH aims to achieve a proper balance between societal, economic and environmental objectives, and attempts to efficiently use the scarce and scattered information available on the majority of substances. Thereupon REACH aims to reduce animal testing by optimized use of in silico and in vitro information on related compounds.
The REACH regulation advocates the use of non-animal testing methods, but guidance is needed on how these methods should be used. The procedures include alternative methods such as chemical and biological read-across, in vitro results, in vivo information on analogues, (Q)SARs, and exposure-based waiving. The concept of Intelligent Testing Strategies for regulatory endpoints has been outlined to facilitate the assessments. Intensive efforts are needed to translate the concept into a workable, consensually acceptable, and scientifically sound strategy.
CADASTER aims at providing the practical guidance to integrated risk assessment by carrying out a full hazard and risk assessment for chemicals belonging to four compound classes. A Decision Support System (DSS) will be developed that will be updated on a regular basis in order to accommodate and integrate the alternative methods mentioned above. Operational procedures will be developed, tested, and disseminated that guide a transparent evaluation of four classes of emerging chemicals, explicitly taking account of variability and uncertainty in data and in models.
The aim of this presentation is to exemplify the integration of information, models and strategies for carrying out safety-, hazard- and risk assessments for large numbers of substances. It will be whosn how real risk estimates can be delivered according to the basic philosophy of REACH of minimizing animal testing, costs, and time, thus showing how to increase the use of non-testing information for regulatory decision whilst meeting the main challenge of quantifying and reducing uncertainty.

**RA11-3**

**Towards guidance on how to characterize prediction uncertainty in QSAR regression models within the CADASTER project**

**A framework for hazard assessment under data-scarce conditions: the transformation product problem**

CA Ng[1], M Scheringer[1], K Fenner[2], K Hungerbuhler[1]
[1]ETH Zurich, ZURICH, Switzerland
[2]Eawag Swiss Federal Institute for Aquatic Science and Technology, DUBENDORF, Switzerland

The European Union's REACH legislation requires that transformation products be included in chemicals assessment for chemicals produced or imported in amounts exceeding 100 tonnes per year. However, including transformation products in such assessments could be considered an intractable problem, given the paucity of available data and the difficulty of predicting the most likely transformation route from the many possible degradation products of a complex parent chemical (the so-called 'combinatorial explosion' problem). We have developed a scheme that seeks to overcome these data and knowledge gaps to identify transformation products that substantially contribute to the persistence of a parent chemical and its substance family. This is accomplished through the integration of methods to predict biodegradation products, to estimate physico-chemical properties and environmental half-lives, and to calculate the joint persistence, a metric that includes both the emitted chemical and its transformation products. Our results highlight that the 'combinatorial explosion' problem can be managed, but there remains a serious need for better quality data, particularly for the environmental half-lives of chemicals.

**RA11-5**

**ITS implementation and acceptance: investigating the stakeholders' perspective?**

S Gabbert
University of Wageningen, WAGENINGEN, The Netherlands

The comprehensive data requirements of REACH, the animal welfare concerns put forward by REACH, and the large number of industrial chemicals that are going to be tested require a "paradigm shift"of the current risk assessment and risk management regime for industrial chemicals from a extensive hazard testing to a risk-driven approach. In this context, Intelligent or Integrated Testing Strategies (ITSs) (i.e. sequential combinations of existing human and physicochemical data, testing and non-testing information, and exposure information) have been considered appropriate tools for more efficient and flexible toxicity testing.
However, little information has become available so far about the users' perspective on ITS development and implementation. This is the more important as the ITSs that have been developed within the past years will be used only if they respond to the users' needs.
The aim of this study is, therefore, to investigate the stakeholder's view on the development, use and implementation of ITSs and to investigate the needs for further research. For this purpose qualitative, semi-directed stakeholder interviews were performed with members from different stakeholder groups (industry, science, regulatory agencies, consultancies, animal protection interest groups). The paper presents and discusses the results of the interviews.
Our results show that there does not exist a commonly agreed definition of what an ITS. Furthermore, we observed that the stakeholders have different viewpoints regarding the potential use, the strengths and the limitations of ITSs in a regulatory context. Our study confirms that ITSs are generally considered useful tools for reducing the need for animal testing. The stakeholders emphasized various aspects for a more systematic development and use of ITSs.
In addition, our study underlines the crucial role of risk and uncertainty communication in order to improve ITS implementation and acceptance.

**RA11-6**

**The OECD QSAR Toolbox - version 2.0**

S Dimitrov[1], TP Pavlov[1], TS Schultz[2], RD Diderich[2], DH Hirmann[3], TN Netzeva[3], OG Mekenyan[1]
[1]University Prof. Assen Zlatarov, BOURGAS, Bulgaria
[2]Organization for Economic Co-Operations and Development, PARIS, France
[3]European Chemical Agency, HELSINKI, Finland

The first version of the OECD QSAR Toolbox was publicly released in March 2008. The Toolbox is a software application intended to be used by governments, industry and other stakeholders to fill gaps in (eco)toxicity data needed for assessing the hazards of chemicals. It contains databases with results from experimental studies, grouping engine, a library of QSAR models, tools to estimate missing experimental values, and report editor.
Since October 2010 the OECD QSAR Toolbox version 2.0 is available for free and could be downloaded from the OECD website. For the first time in Version 2.0 there is a distributed version along with a stand-alone version. Also, with Version 2.0, new downloads are accessible via auto-updates. This release is part of a four-year collaborative project between OECD, ECHA, LMC and other partners.
The aim of this presentation is to elucidate the improvements of the main functionalities of the new version of the Toolbox: Input, Profiling, Endpoint, Category Definition, Data Gap Filling and Report, as well as the new features introduced in version 2.0 of the Toolbox. Key change in second version compared to the first version is the improved user interface to make the Toolbox more intuitive and user-friendly. The key mechanistic profilers were refined, and new databases were added. The new version of the QSAR Toolbox allows also users to import/export data from and to IUCLID 5, and suitable reporting of the results. The system infrastructure was also improved in order to address the numerous other requirements of the growing number of users. Currently, based on the user comments, we are working on the next version 2.1 which will be releases in mid February 2011

## RA12 - Risk communication for environmental protection: Scientific and regulatory needs

**RA12-1**

**Development of realistic and effective risk mitigation measures within authorisation of hu-**

**man and veterinary pharmaceuticals**

M Liebig[1], C Floeter[2], T Hahn[3], W Koch[4], A Wenzel[5]
[1]ECT Oekotoxikologie GmbH, FLOERSHEIM/MAIN, Germany
[2]Science & Law Consult, HAMBURG, Germany
[3]Fraunhofer Institute for Toxicology and Experimental Medicine - ITEM, HANNOVER, Germany
[4]Federal Environment Agency (Umweltbundesamt), DESSAU, Germany
[5]Fraunhofer Institute for Molecular Biology and Applied Ecology - IME, SCHMALLENBERG, Germany

Human and veterinary pharmaceuticals are released continuously into the environment in amounts which are comparable to those of pesticides. Therefore, potential environmental risks have to be assessed according to legal requirements within registration and authorisation procedures for pharmaceuticals. If an unacceptable risk for the environment is indicated, risk mitigation measures (RMM) should be proposed by the applicant and implemented within risk management procedures.
The authorisation of a veterinary pharmaceutical can be refused due to specific environmental concerns, whereas for human pharmaceuticals a refusal due to environmental concerns is not envisioned. So far, RMM have been applied only for veterinary pharmaceuticals. Depending on the registration procedure (decentralised, centralised, mutual recognition or national procedures), the year of authorisation and the reference member state, RMMs for the same active ingredient can differ significantly. For human pharmaceuticals, feasible and effective risk mitigation measures are not yet available.
Therefore, within a R&D-project funded by the German Federal Environment Agency (UBA), risk mitigation measures to reduce environmental risks posed by veterinary and human pharmaceuticals were identified, evaluated and further developed. The RMMs will be assessed according to their practicability, efficiency, sustainability, verifiability and their compliance with national and European regulations. As one of the outcome of this project a catalogue of risk mitigation measures will be compiled which serves likewise applicants and authorities within authorisation procedures of human and veterinary pharmaceuticals. The application of these RMM may lead to more harmonisation, transparency and equal treatment within authorisation of medicinal products.

**RA12-2**

**Communication about environmental risks of human pharmaceuticals and the therapeutic desires of patients: is there an overlap?**

R Laenge[1], K Heuck[2], H Blode[1], D Bernuit[1], A Filonenko[1]
[1]Bayer Schering Pharma AG, BERLIN, Germany
[2]Bayer HealthCare AG, LEVERKUSEN, Germany

Potential environmental risks of human pharmaceuticals are a subject of growing interest in the scientific and regulatory community as well as in the general public. Evaluation of the environmental risk assessments and the discussion on consequent management options focus primarily on the environmental impact but rather little on the desire of the patients for optimal therapeutic treatment. This produces uncertainties amongst the stakeholders in the public health system about the actual extent of the problem and the urging needs for regulatory actions.
In this context, a classification system of medicinal products was introduced in Sweden as a tool for communicating environmental risks to the involved parties, in order to support the possibility of selecting the medical treatment with the potentially lowest environmental impact. This system is accessible to the public and provides information in form of summary statements of environmental risks or hazards as well as detailed study results for the specialist. It was proposed to be extended across the European Union. However, results of a previous survey on the success of this system to influence prescription and use patterns are not very promising. One reason for this lack of success may be the dilemma that the environmental concerns are not in accord with the desire of patients for optimal treatment even in a society such as the Swedish with a reputation of high environmental concern.
As a better communication method, an assessment which describes benefits, potential environmental and socio-economic risks, and possible management options may provide a more balanced view on public health needs and the legitimate concerns for an intact environment.
As an example, we summarize a socio-economic impact assessment of the steroid hormone ethinylestradiol, a component of the birth control pill, which has been has been described as an endocrine disruptor in surface waters, but which benefits are rarely been discussed in similar scrutiny outside the field of medical specialists.
In essence, we propose a socio-economic impact assessment as an appropriate approach to communicate benefits, potential environmental and socio-economic risks, and management options. Although rather complex, this approach may better serve the differentiated information requirements about the various aspects of the use of certain groups of medicines as just a classification system regarding environmental risks.

**RA12-3**

**The application of CLP/GHS to pesticides: impact of new hazard communication element**

E Andreini[1], GG Garramone[1], TM Mammone[1], AM Moretto[2]
[1]Azienda Ospedaliera - Polo Universitario "L.Sacco", MILANO, Italy
[2]Università degli Studi di Milano, Depart. Environ. and Occup. Health, MILANO, Italy

CLP Regulation is the new EU Regulation on Classification, Labelling and Packaging of chemical substances and mixtures. It introduces a new system for classification and labelling of chemicals, based on the Globally Harmonised System of Classification and Labelling of Chemicals (GHS), an attempt to provide an international guidance on standardized label elements and safety data sheets.
CLP/GHS criteria establish new hazard communication elements which are, to a great extent, different from those currently used in Europe. As a consequence, each chemical substances placed on the EU market will be checked and then reclassified and relabelled as needed.
New elements will be applied to all chemicals used in the workplace as well as by consumers, and in particular to pesticides. Pesticides labelling is an important device to provide practical information about their hazards and handling, as well as to ensure a safe use and management of risks for man and the aquatic/terrestrial ecosystem. Plant protection products (PPP), in fact, represent mixtures with intrinsic hazardous properties which are intentionally released into the environment.
The implementation of CLP/GHS in EU will involve a long transition period to allow pesticide manufacturers to comply with new criteria, and customers (farmers) to become familiar with new hazard communication elements. Thorough information campaign targeted to stakeholders in chemical supply chain, including consumers, should be performed and the level of response continuously monitored.
Aim of the project is to investigate difficulties and probable gaps encountered by downstream users of the pesticides supply chain in complying with the new CLP/GHS classification rules and with the new hazard communication elements. Five different targets (pesticide retailers, trade-unions, personnel employed in Public Occupational Health Services, pesticide professional users, and pesticide manufacturers) established in Lombardy Region (Italy) were selected. Questions were related to the pictogram meaning, the right check of PPP labelling, the need of specific training course, the need of press aimed campaigns.
Preliminary results concern basic knowledge or any information about the new regulation. Some gaps and problems emerged, and results were used as a basis to produce a simple illustrated leaflet displaying the incoming changes, to be distributed to professional users and to consumers.

**RA12-4**

**To inform or not to inform, that is the question**

AM Wester
The Royal Insitute of Technology, STOCKHOLM, Sweden

Risk communication is an area that has received great attention in the last few years as it is recognized that communication is a necessity for addressing pressing environmental concerns. The ambition of risk communication can also be a bit more modest or local, where a need for risks to be properly communicated between producers and a larger audience is important for reducing risks to the environment or health on a local level. This contribution presents the results from findings from a survey study performed among producers of articles in order to investigate how they inform or communicate potential risks with their customers (N=101). Five types of articles were identified: textiles, shoes, tires, home electronics, and PVC flooring. The results show that producers of articles that may contain chemicals that can pose a threat to either human health or the environment have good information about what their products contain. This information is primarily used for the internal environmental work, and not for communicating with consumers. However, customer interaction is high and the most producers in this study are willing to make changes in their production, when this is possible, as a result of this interaction. However, the overall impact of consumer or public perception has weaker influence on actions taken to reduce the negative environmental impact of production. The most common way of communicating or informing consumers about what the products contained was trough labeling and tables of content. The least utilized way of reaching consumers was providing contact information. It Is concluded that that the most common way of reaching consumers with information on possible negative environmental and health impacts with goods and articles were by providing information on the product itself and the least common was to provide contact information, which in practice can deter consumers from communicating directly with the producers. It is argued that legislation seems to be the most powerful tool in encouraging producers to reduce possible negative effects with their production, the requirement and form for communication must be formally regulated in order to reach its intended impact.

**RA12-5**

**How can the cautious policy of acceptance 'case-by-case' become a mechanism of progress towards the rigorous, successful and extensive use of QSARs within REACH?**

S Pardoe[1], E Benfenati[2], G Gini[3], C Mays[4]
[1]PublicSpace Ltd., ULVERSTON, United Kingdom
[2]Istituto Mario Negri, MILANO, Italy
[3]Politecnico di Milano, MILANO, Italy
[4]Institut Symlog de France, PARIS, France

Current policy on the use QSAR models within REACH is to accept each use 'on a case by case basis'.[1] This is also described as a 'learning by doing approach'.[1]
This familiar 'case by case' policy can be viewed by industry, regulators and QSAR developers as a necessary and responsibly cautious approach, but it can also be viewed as a frustrating barrier to regulatory clarity and the increased use of QSARs. The process of industry learning from cases also becomes challenging in a context where cases are diverse and subject to commercial confidentiality.
In the presentation we therefore contribute to the discussions of what is needed to support this important process of 'learning by doing' and so hasten the 'case-by-case' progress towards the rigorous, successful and extensive use of QSARs to reduce animal testing.
Specifically, we will draw out key themes from the ECHA guidance for industry registrants, and from ECHA's initial observations from registration dossiers (presented in seminars and available online). We will also draw on insights from an interview and discussions with ECHA and from a survey and an international workshop with industry, regulators and QSAR developers. The first author draws on research experience in applied linguistics and science & technology studies (STS), specifically on science communication, learning professional genres, science and documentation issues in environmental assessment, and public debate around the 'case by case' UK GM crop trials. The presentation is therefore the result of dialogue, and applies social science insights to the policy, science and technology of toxicology and QSARs.
We suggest that the existing ECHA guidance documents provide a strong basis for potentially flexible and responsive practice, and that ECHA's initial seminar 'observations from registration dossiers' are a first step in the process of 'documenting the learnings'.[1] The further challenge is to understand the 'unacceptable' submissions in order to guide a diverse network of professionals in a contingent and reflexive activity. We offer a conceptual framework to support and develop this process.

[6]Universitaet Stuttgart, STUTTGART, Germany

There is a large debate about the possible use of QSAR models for REACH. Indeed, REACH requires that no animal experiment is done, unless other approaches are not possible or have failed. QSAR models can be useful for many reasons: they bring innovation; they counteract problems related to the issues posed by animal tests for the necessary time, animal lives, number of laboratories; they are cheaper, can be used for thousands of chemicals allowing fast prioritisation, and offer possibility to plan safer chemicals in advance.
Within REACH QSAR models are foreseen for 1) risk assessment, 2) classification and labeling, and 3) prioritization. There are several QSAR models with different features, which are appropri-

ate for one or more scope.
The use of QSAR for risk assessment within the substance registration is a demanding task. In this case the model uncertainty has to be low. It is important to compare the uncertainty associated to the experimental model, with that of the QSAR model.
The use of QSAR models for classification and labeling (C&L) has different requirements, regarding the use of continuous or categorical values, and the associated uncertainty. QSAR models may offer a systematic way to provide C&L of the substance.
Prioritization has also different requirements. In this case the uncertainty of the model is not a major barrier. The tools for prioritization can be also different from those used within the C&L approach, since it may be useful to summarize the results for different endpoints.
These different requirements, use and kind of QSAR models, demands different ways to communicate the results, in particular for the uncertainty and the details of the QSAR models. However, some general issues have to be addressed. As requested by REACH, a description of the limitations of the model has to be done, addressing the applicability domain of the model. To clearly explain this has a major influence on the QSAR acceptability.
Further discussion will address the features, use and possible acceptance of QSAR models depending on the case where they are used within a conservative or realistic perspective, which has also implications on the strategies of integrating results from different models. The role of QSAR experts, and how to make objective the explanation on the results, will be also addressed.

## RA13 - The future of ecotoxicological risk assessment - biological traits, ecological vulnerability, improved SSDs, indirect ecological effects

**RA13A-1**

**Considering protected aquatic non-target species in the environmental risk assessment of plant protection products**

EF Liess[1], M Kattwinkel[1], M Beketov[1], O Kaske[1], H Steinicke[1], M Scholz[1], K Henle[1], S Duquesne[2], J Wogram[2]
[1]UFZ, LEIPZIG, Germany
[2]3Federal Environment Agency (UBA), DESSAU, Germany

Maintaining biodiversity when using plant protection products is aimed for by the new regulation for the placing of PPPs on the market (EC, 1107/2009). A relevant aspect of biodiversity are endangered and also protected species that have a scattered but widespread distribution in agricultural habitats. Therefore, they need to be considered within the risk assessment framework of PPPs. Here we explore whether the current risk assessment framework safeguards protected species as defined in the Habitats Directive (92/43/ EEC, 1992).
Reviewing information on the effects of toxicants, we conclude that protected species with regard to their toxicological sensitivity seem to be comparable to non-protected species. However, sensitivity of protected species may be increased in the environmental context, as typically found for individuals and populations under stress. Also population recovery is often slower compared to many non-protected species as protected species often have comparably long generation times.
We conclude that the toxicological context sensitivity on the individual- and the population level of endangered and protected species is higher compared to non-protected species. Therefore, we suggest exploring whether for endangered and protected species a higher safety factor in addition to the existing ones should be introduced when extrapolating from laboratory standard test systems. We also suggest not to consider recovery of populations in environmental risk assessment.

**RA13A-2**

**Ecotoxicology and macroecology - time for integration**

MA Beketov, M Liess
UFZ - Helmholtz Centre for Environmental Research, LEIPZIG, Germany

After almost 50 years of development of ecotoxicology, it has become clear that this discipline cannot answer its central questions, such as, "What are the effects of toxicants on biodiversity and ecosystem functions and services?" We argue that if such questions are to be answered, a paradigm shift is needed; the current bottom-up approach of ecotoxicology should be merged with a top-down macroecological approach. Furthermore, we show that such integration is currently methodologically possible. To tackle the current pressing challenges, ecotoxicology has to search for the truth using both the bottom-up and top-down approaches, similar to digging a tunnel from both ends at once.

**RA13A-3**

**Cross-effects of metallic contamination and parasitism on zebra mussel physiology**

L Minguez[1], A Boiché[1], J Bouquerel[1], N Brulé[1], S Mastitsky[2], DP Molloy[3], S Sroda[1], L Giambérini[1]
[1]Laboratory LIEBE, UPV Metz, CNRS UMR 7146, METZ, France
[2]Buffalo State College, Great Lakes Center, NEW YORK, United States of America
[3]Division of Research and Collections, New York State Museum, ALBANY, United States of America

In the framework of environmental risk assessment, parasites could represent a confounding factors interacting with other stress factors, like pollution. Among freshwater macroinvertebrates used in bioindication procedures, zebra mussels (Dreissena polymorpha) are considered a reliable bioindicator species. However, like many other organisms, it can be parasitized. Our previous studies underlined a positive correlation between metallic contamination, particularly by Chrome and Nickel, and the infection prevalence of Ricketsiales-like organisms (RLOs).
Moreover, our in situ observations revealed that parasitism can be a confounding factor in ecotoxicological by modifying host physiological responses. We thus performed experiments in laboratory controlled condition specifically focused on Dreissena-Ophryoglena and Dreissena-RLOs systems to investigate the cross effects of parasite infection and nickel contamination.
Zebra mussel specimens were sampled in a site on the Meuse River with low trace-metal concentrations. After acclimatization, the mussels were exposed to 0, 20 µg Ni.L-1 (French legal limit of concentration in drinking water) and 500 µg Ni.L-1 (French legal limit of concentration of industrial discharge) during 48 hrs. Parasite infection capacities were assessed all along the experiment (0, 24 and 48 hrs). After 48 hrs of exposure, cell parameters in the digestive gland such as structural changes of the lysosomal and peroxysomal systems, and neutral lipid and lipofuscine granule accumulation were measured by histochemistry and automated image analysis. The immune capacities of mussels (i.e. total hemocyte counts, differential hemocyte counts, phagocytosis capacity, production of reactive oxygen species and the lysosomal activity) were also evaluated by flow cytometry. An increased prevalence rate and a decreased infection intensity were observed: at the end of the experiment, there were two-times more infected mussels presenting a lower number of parasites per individual. This indicates a rapid infection from the initially infected mussels. Moreover, a tendency to a decrease of the immune system capacities was measured (e.g. a reduction of phagocytosis, more reactive oxygen species produced). In a larger context, this study highlights the potential risk of Bivalvia species subject to multiple environmental stress factors such as parasitism and chemical contamination.

**RA13A-4**

**Xplicit, a novel approach in probabilistic spatiotemporally explicit exposure and risk assessment for plant protection products**

T Schad[1], GG Görlitz[1], RS Schulz[2]
[1]Bayer CropScience AG, MONHEIM, Germany
[2]University Landau, LANDAU, Germany

The quantification of risk, the likelihood and extent of adverse effects, is a prerequisite for regulatory decision making for Plant Protection Products and the goal of the Xplicit project. In Xplicit, realism is increased in the exposure and risk assessment (ERA), first by using real-world data on, e.g., landscape and agronomic factors affecting exposure; and second, by taking the variability of key factors into account. Spatial and temporal variability is explicitly addressed. Scale-dependencies (e.g., of variability) are taken into account. This allows for risk quantification at different scales: e.g., at landscape scale, an 'overall picture' of the potential exposure of non-target organisms can be derived (e.g., for all water bodies or off-crop habitats in a given landscape); at local scale, exposure might be relevant to assess recovery and recolonisation potential; intermediate scales might best refer to population level and hence, might be relevant for risk management decisions (e.g., water body stretch, or individual off-crop habitats). The Xplicit approach is designed to comply with a central paradigm of probabilistic approaches, namely that each individual case that is derived from the variability functions employed should represent a potential real-world case. This is achieved by operating spatiotemporally explicit. Landscape factors affecting the local exposure of habitats of non-target species (=receptors) are derived from geodatabases. Variability in time is resolved by operating at discrete time steps, with the probability of events (e.g., application) or conditions (e.g., wind conditions) defined in Probability Density Functions (PDFs).
The propagation of variability of parameters into variability of exposure and risk is done using a Monte Carlo approach. Among the outcomes are expectancy values on the realistic worst-case exposure (Predicted Environmental Concentration, PEC), the probability P that the PEC exceeds the EAC (Ecologically Acceptable Concentration) for a given fraction of habitats, and risk curves. The outcome can be calculated at any ecologically meaningful organisation level of receptors. Xplicit uses a modular and object-oriented software design that facilitates cooperation between the different disciplines. An example application of Xplicit is shown for a hypothetical risk assessment for Non-Target-Arthropods (NTAs), demonstrating how the risk quantification can be improved compared to the standard deterministic approach.

**RA13A-5**

**Effects of time-variable exposure of isoproturon on green algae under flow-through conditions - modelling and experimental results -**

S Weber[1], TG Preuss[2], HT Ratte[2], M Dorgerloh[3], D Schaefer[3], E Bruns[3], G Goerlitz[3]
[1]Harlan Laboratories Ltd., ITINGEN, Switzerland
[2]RWTH Aachen University, AACHEN, Germany
[3]Bayer CropScience AG, MONHEIM AM RHEIN, Germany

Due to the impact that plant protection products may have on aquatic ecosystems, extensive laboratory toxicity studies and risk assessments are required before a product can be registered in the European Union. Predicted environmental concentrations in surface water bodies ($PEC_{SW}$) are calculated based on realistic worst-case exposure scenarios defined by the FOCUS group. They reflect that aquatic exposure is often characterized by multiple peaks of variable height and duration, driven by spray drift input as well as run-off and drain flow events. Relating the results of standard ecotoxicity tests performed under constant exposure to FOCUS time-variable exposure patterns is only possible by gross simplifications and the use of worst-case assumptions. In order to refine this approach, knowledge about the responses of aquatic organisms (e.g. green algae) to time-variable exposure needs to be gained for more realistic but nevertheless conservative risk assessments. One way forward is the use of population models within the higher-tier risk assessment, in close combination with ecotoxicological experiments. In order to address the above problems in the case of algae, the aim of this work was to establish a flow-through test system in combination with mathematical modelling for the assessment of effects of time-variable exposure of pesticides on populations of the green algae *D. subspicatus* and *P. subcapitata*.
The flow-through system was developed and applied to assess the effects of isoproturon on the selected algae. A FOCUS exposure pattern was generated for isoproturon and a simplified version was used in the test system. In parallel, an algae population model was developed that is able to describe the population density of relevant algal species in dependence of variable environmental conditions (nutrients, light, and temperature) and the presence of toxicants.
The experimental results show a recovery of the algae after each exposure peak. The developed algae model is able to describe population dynamics in a flow-through system under exposure of isoproturon in close agreement with the experimental data. The model predictions were successfully verified by the experiments and the flow-through system in combination with the algae population model is a promising higher-tier tool to assess the effects of time-variable exposure on algae. The results make it possible to evaluate the potential of an algae population to recover after pulsed exposure patterns.

**RA13A-6**

**Setting environmental quality criteria for groundwater: a comparison of current approaches**

GC Hose[1], MJ Lategan[2], K Raynel[1]
[1]Macquarie University, SYDNEY, Australia
[2]University of Technology, SYDNEY, Australia

Environmental quality criteria for groundwater have to date been largely based on guidelines for surface water protection, drinking water standards, or the analytical detection limits of some pollutants, with little consideration of the inherent value and protection of groundwater ecosystems per se and their unique biota. Importantly, risk-based approaches, such as species sensitivity distributions, that are widely advocated and used for setting surface water criteria have not been used for setting criteria for groundwater ecosystems, largely because of the lack of toxicity data specifically for groundwater biota.
Using toxicity data derived for groundwater invertebrates and microbial assemblages from aquifers in eastern Australia, we derive environmental quality criteria for common groundwater contaminants using a risk-based approach. We compare the degree of protection offered by the various approaches for criteria setting discussed above, compare our criteria for groundwater against existing criteria used in Australia and Europe, and consider future directions for groundwater ecosystem protection in light of the paucity of relevant toxicity data now and into the future.

**RA13B-1**
**SSDs - Good idea, bad practice**
R Fox
University of Melbourne, PARKVILLE, Australia
The concept of a Species Sensitivity Distribution (SSD) appeared more than 20 years ago. Since that time it has been widely used as the basis for establishing so called 'safe concentrations' for chemicals in the environment. While seemingly well-grounded in statistical theory the SSD lacks a credible nexus between statistics and ecology. Furthermore, the integration of statistics and ecotoxicology has been patchy resulting in a lack of statistical rigour in some aspects of ecotoxicological practice - the impact of which is neither fully understood nor appreciated.

**RA13B-2**
**A Bayesian approach to probabilistic ecological risk assessment using SSDs: risk comparison of nine toxic substances in Tokyo surface waters**
TI Hayashi[1], N Kashiwagi[2]
[1]National Institute for Environmental Studies, TSUKUBA, Japan
[2]The Institute of Statistical Mathematics, TACHIKAWA, Japan
Quantitative risk comparison of toxic substances is necessary to decide which substances should be prioritized to achieve effective risk management. We compared the ecological risk of nine toxic substances (ammonia, bisphenol-A, chloroform, copper, hexavalent chromium, lead, manganese, nickel, and zinc) in Tokyo surface waters by adopting an integrated risk analysis procedure using Bayesian methodology. Species-sensitivity distributions of these substances were derived by using four separate models. These models were different in the assumption about sensitivity differences at taxonomic group level. We then computed deviance information criterion values of the models and compared them to select the model with the best predictive ability. In the estimation of SSD, an advantage of our approach is that we are able to correct potential biases in the proportions of taxonomic groups in the ecotoxicity data. Environmental concentration distributions were derived by a hierarchical Bayesian model that explicitly considered the differences between within-site and between-site variations in environmental concentrations. Medians and confidence intervals of the expected potentially affected fraction (EPAF) of species were then computed by the Monte Carlo method using Markov chain Monte Carlo samples of the posterior distributions of species-sensitivity and environmental concentration distribution parameters as input values. The estimated EPAF values suggested that risk from nickel was highest and risk from zinc and ammonia were also high relative to other substances. The risk from copper was highest if bioavailability was not considered, although toxicity correction by a biotic ligand model greatly reduced the estimated risk. The risk from manganese was highest if a conservative risk index estimate (90% upper EPAF confidence limit) was selected. The presented risk analysis procedure using EPAF and Bayesian statistics is expected to advance methodologies and practices in quantitative ecological risk comparison.

**RA13B-3**
**Developing a Species Sensitivity Distribution curve with Arctic species exposed to petroleum compounds and comparison with temperate species**
GH Olsen[1], S Smit[2], J Carroll[1], I Jæger[1], T Smith[1], L Camus[1]
[1]Akvaplan-niva, TROMSØ, Norway
[2]Statoil AS, TRONDHEIM, Norway
To identify and manage potential impacts associated with increased activities in arctic regions reliable risk assessment approaches for the arctic environment are required. Toxicity data on arctic species are, however, lacking and it is unsure if available toxicity data on temperate species also represent the sensitivity of arctic species. We performed toxicity test with 2-methyl naphthalene with 11 arctic and 6 temperate species from different functional groups. Based on the test results we constructed an arctic and a temperate Species Sensitivity Distribution (SSDs). The distributions were compared to determine whether arctic and temperate species differ in their sensitivity to 2-methyl naphthalene. Median estimates for the hazardous concentrations affecting 5 and 50 percent of the species (HC5 and HC50) based on both no effect concentrations (NEC) and 50% lethal effect concentrations (LC50) were up to a factor 2 higher for temperate species then for arctic species. However, due to overlapping uncertainty intervals around the median estimates of the arctic and temperate HC5s and HC50s, we cannot conclude that this factor of two actually indicates a difference in sensitivity between arctic and temperate species.

**RA13B-4**
**Extending the SSD concept to explore some foundational model limitations: a Bayesian hierarchical approach**
GL Hickey[1], PS Craig[1], S Marshall[2], O Price[2], MGD Smit[3], A Hart[4], R Luttik[5], P Chapman[2], D de Zwart[5]
[1]Durham University, DURHAM, United Kingdom

[3]Statoil ASA, TRONDHEIM, Norway
[4]The Food and Environment Research Agency, YORK, United Kingdom
[5]RIVM, BILTHOVEN, The Netherlands
Species sensitivity distributions (SSDs) are statistical constructs which model interspecies variation of sensitivity to a particular toxic stressor. The current REACH technical guidance document permits the application of SSDs in risk assessment, subject to a number of criteria. Notwithstanding noteworthy criticism received, the SSD is considered by regulators to be a pragmatic model for extrapolating to environmental toxicant concentrations of concern. The manner in which SSDs are currently applied is implicitly dependent on a number of (overlapping) statistical and ecological assumptions. These include (but are not limited to): (1) the measured species toxicity values being precisely known; (2) independence of SSDs for each separate chemical risk assessment; (3) *a priori* exchangeability of species toxicity values; (4) no correlation between species.
In this research we propose a model which generalizes the SSD concept to include chemical effects and shared species effects. It offers flexibility to address or refine each assumption by hierarchically adding layers into the model. Models are fitted to RIVM and US EPA acute-effect toxicity databases under a Bayesian statistical framework to allow for transparent quantification of and flexible propagation of uncertainty. Important insight is gained from the inclusion of 'species effects' modelling which, expectedly, indicates increasing differences as taxonomic distances in SSDs increase. The magnitude of measurement error estimated, based on within taxa homogeneity, which also properly accounts for censored measurements, is likely to be of significance to risk assessors and warrant further consideration in either modelling framework. The current quasi-meta-analysis approach towards aggregating multiple chemical-species data points is untenable from an uncertainty viewpoint.
Initial results indicate deficiencies in the current SSD concept, thus reducing the credibility and meaningfulness of any subsequently derived hazardous concentrations. Other recent model proposals which act as precursory tools to SSD modelling may not sensibly propagate uncertainty and/or succumb to modelling contradictions. A hierarchical model may overcome this, however will require a more radical approach to defining protection goals and environmental concentrations of concern.

**RA13B-5**
**Species sensitivity distributions: how they can be improved?**
BJ Kefford[1], RB Schäfer[2], L Liess[3], StJ Michael[4]
[1]University of Technology Sydney, BROADWAY, Australia
[2]University Koblenz-Landau, LANDAU, Germany
[3]UFZ-Helmholtz Centre for Environmental Research, LEIPZIG, Germany
[4]CSIRO, GLEN OSMOND, Australia
Species sensitivity distributions (SSDs) are cumulative distributions of species' physiological sensitivity to toxicants. An attractive attribute of SSDs is that they allow the severity of a particular concentration of a chemical to be estimated in terms of the potentially affected fraction of species. The severity of a pollution event is a critical component of risk: the severity of an undesirable event and the probability that it will occur. However estimates of the potentially affected fraction of species from SSDs are contingent on several assumptions that are unlikely to be met in conventional uses of SSDs. Recently various novel experimental, field and/or statistical methods have been suggested that will result in SSDs that better meet their assumption. At the same time there is growing recognition that physiological sensitivity of species to toxicants (as measured in laboratory tests) is only one aspect which will influence the response of populations to toxicants. Modelling a species' population will provide better estimates of the likely effect of chemicals on its population but is unlikely to be feasible for a large and representative sample of species from environments/regions of interest. The combining of resilience traits (e.g. generation time and dispersal capacity) and an avoidance trait (e.g. spending a significant part of the life-cycle removed from the contamination) and physiological sensitivity has proven very useful in developing biological indexes that can indentify community level impacts from specific classes of chemicals. Here we examine how these traits might be combined with physiological sensitivity to make SSDs that describe both types of sensitivity and review suggested developments to SSDs. We conclude that there are modifications that will improve the use of SSDs but that their widespread adoption is not a purely technical issue.

**RA13B-6**
**On correct interpretation of Species Sensitivity Distribution output through eco-epidemiological analyses**
L Posthuma, D de Zwart
RIVM, BILTHOVEN, The Netherlands
Species Sensitivity Distributions are statistical distributions which relate the concentration of a toxic compound (X) to the Potentially Affected Fraction (Y) at that concentration, with their oldest use being the derivation of protective Environmental Quality Criteria from laboratory ecotoxicity test data. Such protection-aimed EQCs, like the HC5 (the Hazardous Concentration for 5% of the species, also known as the 95%-protection criterion), are used in environmental policy to protect ecosystems from ecotoxic effects. There are also EQCs which trigger further research or remediation (e.g., the HC50). Despite this use in ecosystem protection or risk reduction, there is no ecology in these SSDs at all. Hence, questions have been posed on the whole idea of SSDs in relation to ecosystem protection and management.
This paper is concerned with the interpretation of SSD-output.
We have studied various large-scale (bio)monitoring data sets, in which each of the sampling points is characterized by a suite of environmental parameters as well as toxic compound mixtures. We found, that there is an association between the predicted toxic pressure of mixtures across sites and the magnitude of local impacts on the local taxa. Various types of association are shown. While this type of approaches evidently does not 'validate' the SSD-model, our analyses certainly give answers to questions like: (1) is there any relation between SSD-predicted impact and observed impact? (2) if so, is the relationship as expected (higher toxic pressure, higher impacts)? and (3) if so, what is then the use of SSDs in practice? We argue, that SSD-output is of use as ranking tool in various contexts, ranging from protection of ecosystems against chronic exposures, as well as environmental disasters involving toxic chemicals.

**RA13C-1**
**Purposefully-quantified traits and kinetic parameters as predictors for intrinsic sensitivity**
N Rubach[1], J Baird[2], J Maund[1], J van den Brink[3]
[1]Syngenta Crop Protection AG, BASEL, Switzerland
[2]Environment Canada and University of New Brunswick, FREDERICTON, Canada
[3]Wageningen University and Alterra, WAGENINGEN, The Netherlands
Current ecological risk assessment (ERA) practices are based on the assumption that taxonomically-related species will show similar sensitivity to toxicants, using safety factors or species sensitivity distributions to extrapolate from tested to untested species. In community ecology, taxonomic approaches place limitations on our description and understanding of species assemblages in nature. Thus, it has been proposed that the systematic inclusion of species traits in ERA could provide a useful alternative insight for prospective approaches. At the same time, there is a growing recognition that the use of conceptual, mechanistic and quantitative models in ERA may improve predictive and extrapolative power. In order to better understand how structural and functional system facets may facilitate inter-species extrapolation we explore how purposefully-quantified traits can be linked to mechanistic effect models in order to predict intrinsic sensitivity. For this we use previously published data on the sensitivity, toxicokinetics and toxicodynamics of a range of freshwater arthropods exposed to chlorpyrifos, employing a purposefully-generated trait data set. The results of a quantitative linking of seven sensitivity endpoints and traits demonstrates that while it is possible to establish meaningful quantitative links between traits and/or trait combinations and process-based (toxicokinetic) model parameters, predicting classical sensitivity endpoints is more elusive. Future research needs include a quantitative linking of toxicodynamic parameter estimations and physiological traits, requiring further consideration of how mechanistic trait-process/parameter links can be used for prediction of intrinsic sensitivity across species and substances in ERA.

**RA13C-2**
**Using functional traits to characterize the effects of pesticides on aquatic macroinvertebrate communities**
A Auber, M Roucaute, L Lagadic, Th Caquet
INRA, RENNES, France
Biological and ecological traits reflect the ability of species to deal with environmental constraints and opportunities. Therefore, they can potentially be used to explain species perfor-

mances and co-existence with other species under particular environmental conditions, including the presence of toxicants. The potential of traits to support a mechanistic link between biological responses and disturbances make them relevant tools to study the relationships between biodiversity and ecosystem functioning. In this 20-month study, the impacts of four realistic pesticide exposure scenarios on trait composition of aquatic macroinvertebrate communities and on leaf litter processing were assessed in outdoor pond mesocosms. The responses of quantitative trophic functional diversity indices combining biological traits and species abundances (QRao and FDis) were also studied. In addition, a new index (Iadd) designed to estimate leaf breakdown rate from the structure of communities was developed and tested. This index is based on the combination of quantitative measurements of a performance trait (shredding efficiency) and abundances for keystone species for litter breakdown. Treatments caused serious impacts on functional attributes of communities and leaf decay. Respiration type was the more discriminating traits influencing the response of macroinvertebrates, which is in accordance with the fact that gills facilitate the assimilation of dissolved toxicants. However, some traits were found relevant for species sensitivity only because they were correlated with other traits, which highlights the importance of considering interrelations between traits to reduce potential errors in interpretation. Both quantitative functional diversity indices showed that trophic diversity was significantly reduced following pesticide treatments, due to an important decrease in the abundance of dead plant feeders. The reduction of leaf decay in treated ponds was a consequence of the effects on dead plant feeders abundance. Iadd proved to be a powerful predictor of leaf breakdown and therefore a promising method for forecasting litter breakdown dynamics from the abundance of keystone species. This work reinforced the idea that trait-based approach may be an efficient tool for understanding the mechanistic effects of chemicals on organisms and their consequences on ecological processes.

**RA13C-3**

**In situ ecological risk assessment using taxonomic metrics and life history traits of macroinvertebrates**

CP Mondy, P Usseglio-Polatera
Université Paul Verlaine - METZ, METZ, France

The European Water Framework Directive (WFD) requires that Member States evaluate the quality of their water bodies using bioindicators like macroinvertebrates. In this work, we aimed at identifying relevant taxonomic and life history based metrics from which we built a first version of a new national tool intended to help experts in identifying stresses from survey of macroinvertebrate communities.

Faunal data comes from the application between 2005 and 2008 of a normalized protocol on 1795 sites distributed through all France (4190 sampling units). Chemical characterization of sites was performed considering 10 anthropogenic stress categories. A set of taxonomic and life history based metrics was calculated for each sampling unit. Considering the available information (chemistry and biology), we selected at least 6 "reference"sampling units (i.e. the least impacted as possible) for each river type (68 river types).

We transformed metric values in standardized deviations from reference. Then we used conditional trees, i.e. dichotomic classification method using Monte-Carlo permutation tests ($\alpha$=0.01; 999 iterations) to decide if groups based on stress status are significantly different considering biological metrics. For metrics that showed a significant response to stress we quantified their Discrimination Efficiency (DE). We selected "generalist"metrics (DE > 30% for at least 7 stress categories) and "specific"metrics (DE > than 30% for at most 3 stress categories). The selected metrics were used to build conditional forests with different combinations of metrics based on their specificity and their DE. These models predict the risk for a sample to come from a stressed station according to its metrics values.

All our "specific"models are pretty good in classifying the samples from reference sites but classify samples from impaired sites with lower efficiency (True Negative Rate between 0.0952 and 0.6892). Incorporating generalist metrics increases the TNR of the models but decreases their specificity.

In this work, we showed that it was possible to construct models that help at establishing a diagnostic on the nature of stress from taxonomic and life history based metrics, we also demonstrated that metrics exhibit a trade-off between specificity and sensitivity and that life history metrics are more important than taxonomic ones in models intended to identify stress rather than detect stress.

**RA13C-4**

**Development of a benthic macroinvertebrate flow sensitivity index for Canadian rivers: can biological traits support the interpretation of species responses?**

G Armanini[1], WA Monk[2], DJ Baird[2]
[1]Prothea, MILAN, Italy
[2]Environment Canada @ Canadian Rivers Institute, University of New Brunswick, FREDERICTON, Canada

Anthropogenic pressure on flow regimes has been recognized as a leading threat to the health of Canadian river ecosystems and their protection requires guidelines based on sound science. To develop ecologically meaningful approaches for the management of riverine ecosystems the interaction between biota and flow variables is a critical step. However, this relationship is poorly understood and, as a consequence, over-simplistic hydrology-based guidelines for river management have been adopted without establishing clear indicators of their success or failure. Here, we support the improvement of guidelines for flow management by presenting a macroinvertebrate-based flow-sensitivity index for Canadian rivers. 2700 biological samples with associated environmental variables were extracted from Environment Canada's Canadian Aquatic Biomonitoring Network (CABIN) database. In addition, biological traits were extracted by two major sources of information on freshwater taxa. A Canadian Ecological Flow Index (CEFI) was developed based on current velocity preferences of common benthic invertebrate families. Tested in a multi-stressor environment, the index strongly responded to changes in hydraulic conditions. The index was further validated using two data sets from the west and east of Canada, indicating its potential nationwide applicability. Biological traits were used to validate the current velocity optima and to explain the response of both the scores and the overall index, helping understating biological properties of the response. In conclusion, we have developed a practical approach to evaluate relationships between flow and an important component of the river ecosystem measured in biomonitoring programs. This has facilitated the development of an index which has good potential as an indicator for the ecological effects of flow alteration. Moreover, we have identified how biological traits can help explain the responses of biological taxa to flow and we have identified a sub set of trait modalities potentially interesting for a development of a traits-based diagnostic for flow alteration.

**RA13C-5**

**Trait-based approach and vulnerability analysis of soil communities affected by pesticide application**

C Vaj[1], CAM van Gestel[2], M Vighi[1]
[1]University of Milano - Bicocca, MILANO, Italy
[2]VU University, AMSTERDAM, The Netherlands

The commonly used tools to assess ecotoxicological risk are lacking ecological realism, because they cannot predict the real consequences for natural communities. In recent years, ecotoxicology has moved towards an improved ecological realism developing new tools capable of accounting for the complexity of ecosystems. In particular, the concept of ecosystem vulnerability is now considerd an essential component of site-specific risk assessment. Vulnerability is defined as a function of sensitivity, susceptibility to exposure and recovery potential after a stress. Trait-based assessment is a tool for predicting vulnerability based on the hypothesis that the vulnerability of different species to a stressor can be predicted from their characteristics.

Though ecosystem vulnerability and trait-based assessment are two promising concepts and are used in modern ecotoxicology, only few studies are available in the literature, especially on the soil compartment.

A field survey was conducted in a vineyard in Northern Italy, under application of pesticides. Microarthropod communities were sampled from the vineyard and from two "control"stations 4 and 10 m outside the plant rows, and identified to the level of taxa (order, sub-order or family level). Morphological, life cycle, physiological and ecological traits were collected for these taxa, to create a big trait matrix. The matrix was intersected with the field survey results to identify which are the traits that cause a major or minor vulnerability to the stress due to pesticide application. The taxa more or less vulnerable were identified according to these traits.

In an alternative approach, traits were divided according to the three components of vulnerability. A score was assigned to each trait according to its relation with vulnerability, which was quantified applying these scores and the trait matrix, using an index. Results were compared to those obtained when using the trait based approach. Similarities and differences between the two approaches will be discussed.

**RA13C-6**

**Soil invertebrates, the poor cousin of TERA ?**

CR Hedde[1], J Cortet[2], J Nahmani[3]
[1]INRA, VERSAILLES, France
[2]LSE, INPL/ENSAIA, VANDOEUVRE-LÈS-NANCY, France
[3]UMR7146 LIEBE, METZ, France

The evaluation and monitoring of soil biodiversity is imperative to assess, understand, model and predict soil functions and its changes. Currently, soil quality measurements take little account of biological components. This is partly since taxonomy-based descriptions of ecosystems limit our ability to depict ecological responses to stress. One way to solve this problem would be to challenge the conventional view of biocenosis towards a perception of invertebrate through their biological/ecological attributes. The challenge is to define how functional traits interact with their environment and each others. This platform presentation we will be split in two parts.

First, we will discuss the reasons why soil invertebrates TERA is not yet developped to date. First, soil is probably one of the most species-rich habitats of terrestrial ecosystems but has received relatively little attention. The second problem is the difficulty of identifying soil invertebrates. One emergent way to solve these problems is the development of metagenomics. Another problem lies on trait ontology inconsistency. Finally, Statzner & Bêche (2010) identified that the greatest obstacle in TERA is the creation of a trait database for many taxa. This difficulty would be overcomed in few years since different intiatives emerge to collect and organize informations in multi-trait, multi-taxon databases.

In a second time we will present some encouraging results on this topic. In a first work, we aimed at elucidating soil macro-invertebrate response to trace metal (TM) contamination. We demonstrated that the shape of functional traits-TM concentration relationships varied, reflecting additive or threshold effects. A second study was dedicated to the early pedogenesis of a technosol built with former coking plant and a combination of thermally treated industrial soil mixed with exogenous organic materials. Three years after Technosol building, our results permit to elucidate different colonisation strategies, and demonstrate the increase of sapro- and geophagous invertebrate that are crucial to organic matter dynamics in the system.

In this communication, we brough some evidences that soil invertebrate TERA can be an alternative to traditional assessement of invertebrate responses to environment and environment changes. However, the improvement of soil invertebrate TERA will require a coordinated international effort to achieve its full potential, by surmounting the currently cited brakes.

**Pollution-Induced Community Tolerance (PICT) in ecological risk assessment - future prospects**

H Blanck
University of Gothenburg, GÖTEBORG, Sweden

There is a gap between the European regulatory systems for hazard and risk assessment of chemicals, and the systems for assessment of ecological and chemical status of ecosystems. This is partly because chemicals in the ecosystems occur as everchanging environmental mixtures for which the joint toxicity is rarely estimated, and partly because short-term, physiologically oriented test systems have only little coupling to important ecological events and processes, including natural selection. Short-term test systems may provide knowledge about the instantaneous sensitivity of a clone or a group of individuals, and might be used to describe mechanism of action and the metabolic syndrome associated with the toxicity of an individual compound. Such test systems also ignore crucial ecological interactions as well as the ability of natural populations to adapt to stressors. In the environment however, organisms will be subject to a variety of selection pressures (natural as well as antropogenic including toxic chemicals). These selection pressures shape populations and the biotic communities of contaminated ecosystems.

Toxicants cannot damage a biotic community in an ecologically relevant way without exerting selection pressure on species or strains of its populations. PICT is an essentially ecological tool based on detection of the outcome/consequences of selection at the community level. During the long-term selection phase of a PICT study, toxicants eliminate sensitive individuals and species and replace them by tolerant ones [1]. In the detection phase any hereby induced community tolerance to suspected toxicants is quantified in short-term tests, in a way that combines the Koch´s rule elements. We suggest that Pollution-Induced Community Tolerance due to its sensitivity, its potential causal links, and its connection to selection processes should be used as a complement to present approaches for describing ecological status.

The aim of the present paper is to outline the procedure for PICT studies in risk assessment and to discuss the possibilities of coupling PICT to other approaches like species sensitivity distributions and metagenomics.

**RA13D-2**

**The effects of varying environmental conditions on the toxicity of mine effluent constituents to coldwater fish**

DL Moore[1], D Poirier[2], P Sibley[1], K Solomon[1]
[1]University of Guelph, GUELPH, Canada
[2]Ontario Ministry of the Environment, ETOBICOKE, Canada

Due to method standardization, current regulations may not afford protection against adverse effects of mine developments under non-standard pH, temperature, and hardness conditions of arctic waters. These effects may be due to liberated minerals, processing by-products, and service community wastes. Canadian mines are controlled under the Fisheries Act, regulating "Any substance that is[3DOTS]deleterious to fish or fish habitat or to the use by man of fish that frequent that water". These regulations limit effluent parameters based on toxicological evidence produced via assay methods published by Environment Canada. For coldwater fish, rainbow trout is used as a surrogate and employs conditions optimal to that species. In contrast, locations of concern exhibit temperatures 10°C colder than standard test conditions, hardness 2-10 times lower than dechlorinated water, and variable pH due to contamination and natural geology.
The study aims to characterize the variability of effluent toxicity across a range of species and conditions while assessing whether the current standard test is protective enough to cover this variation by comparison of standard and 'amended standard' (varied conditions) assays. Eighteen contaminants (NaCl, NaNO2, NaNO3, Na2SO4, KCl, CaCl2, Cd, Cr, As, Cu, Zn, Mg, Ni, Al, MoO4, Se, NH4OH, NaClO, and toluene) were tested using five species of fish native to Northern Canada (arctic charr, lake trout, lake whitefish, round whitefish, and arctic grayling) across a range of pH (5.5, 6, 6.5, 7, 7.5, and 8), temperature (5,10, and 15ð-ðC), and hardness (30, 60, and 120ppm) conditions and their observed effects modeled as 24,48,72, and 96-hour LC50 values.
By comparing these results to each other and to those of the standard rainbow trout test, we have assessed the effect of pH, temperature, and water hardness on contaminant toxicity and time-to-toxic effect within and between species while characterizing the ecological protection afforded by current regulations. The data suggests that, in some instances, the standard has failed to capture the potential toxicity exhibited in non-standard species and non-standard, real-world conditions. Should this variability of non-standard conditions exceed the resiliency of the standard test to act as a surrogate, the mandate of the Fisheries Act to provide adequate protection to fish, fish habitat, and human use of fish will not be met. This potential risk is guiding the project's second phase of research.

**RA13D-3**

**SPEAR index adaptation to lentic/outdoor pond mesocosm studies: an assessment of long term vulnerability to pesticides**

M Roucaute, A Auber, T Caquet, L Lagadic
INRA, RENNES CEDEX, France

Lentic outdoor pond mesocosms are valuable tools for the ecological risk assessment of toxicants, although few synthetic metrics exist to describe overall effects of treatments on the invertebrate communities they host. SPEcies At Risk (SPEAR) metrics have originally been developed for the assessment of the response of river benthic invertebrate communities to toxicant exposure. However, their use for non lotic ecosystems has not been evaluated so far. Such application requires considering the differences between lentic and lotic ecosystems in the species traits used. Both community exposure pattern as well as species mobility were reconsidered in a lentic variant (LSPEAR) we developed. Results of the application of the original SPEAR method, as well as its LSPEAR variant on a dataset obtained during a 16-month long outdoor pond mesocosms study are presented. Benthic invertebrate communities were sampled every 3 weeks in a series of 16 outdoor ponds (9m3, max. depth 0.90m). 12 ponds were split into two groups (CS and LS) treated respectively with mixtures of pesticides corresponding to two alternative Wheat-rape seed crop treatment strategies and 4 ponds were kept as controls. Each of the two classification systems (SPEAR/SPEnotAR and LSPEAR/LSPEnotAR) were compared with the effects on the abundance of macroinvertebrate taxa deduced from Principal Response Curve analysis performed separately for each strategy. PRC showed significant differences between control and treated ponds communities immediately after the beginning of treatments in November 2008 for CS ones and in spring 2009 for LS ponds. All treated ponds communities were restored by late august 2009. According to the original version of SPEAR, 12 taxa out of 54 were supposed to be at risk whereas only 4 taxa met the criteria to be at risk in the LSPEAR. For both treatment strategy, no significant difference was shown for mean bk values between SPEAR and SPEnotAR taxa (Kruskal-Wallis test, p>0.05) whereas a significant difference was shown between LSPEAR and LSPEnotAR taxa, therefore indicating that LSPEAR successfully grouped the most affected taxa according to the PRC. This suggests that the adaptation of SPEAR to lentic systems is feasible but that it necessitates reconsidering the traits used in its construction. It also emphasizes how species composition of pond invertebrate communities may be determinant for their sensitivity and restoration ability after exposure to a toxicant.

**RA13D-4**

**Sensitivity analysis and calibration issues for an aquatic ecosystem model**

C Ciric[1], S Charles[2], P Ciffroy[1]
[1]EDF R&D, CHATOU, France
[2]2Université de Lyon, F-69000, Lyon; Université Lyon 1; CNRS, UMR5558, Laboratoir, VILLEURBANNE, France

In order to assess potential effects of toxicants at the ecosystem level, modeling reveals to be a powerful tool by considering species interactions, and by predicting toxic effects on non-target species populations (indirect effects). The aims of our work are: (i) to develop a new mathematical model which comprehensively describes a whole aquatic ecosystem accounting for species interactions with a clear set of equations including both abiotic and biotic factors; (ii) to perform a sensitivity analysis, i.e., to highlight parameters having the greatest influence on calculated target endpoints in order to simplify further calibration; (iii) to optimize model parameter values using semi-field experimental data from mesocosms; (iv) to incorporate perturbation functions on chosen processes within the model in order to predict potential toxic effects on populations and to identify functional groups at risk.
Following an extensive literature we build a compartmental ecological model for a whole aquatic ecosystem. Compartments include primary producers (macrophytes and algae from phytoplankton and periphyton), primary consumers (juvenile fish and invertebrate grazers, shredders and collectors) and secondary consumers (invertebrate predators and fish). All compartments are related within a food web as well as to abiotic factors like light, temperature and nutriments. We first calibrated and then tried to validate the model on three experimental data sets from mesocosms (specifically, the data from the control mesocosms).
During the talk, the sensitivity analysis method as well as the calibration step approach will be presented in detail for the 'Periphyton-Grazers' sub-model, which constitutes a small prey-predator entity, with a smaller number of parameters (~20) than the complete model (~260). The model calibration provided new values for the parameters that were found to have an important influence on the model output. These values will be presented, during the talk, as well as simulations of the ecosystem dynamics under the non-contaminated conditions. We will finally discuss how the choice of the perturbation functions impacts the ecosystem dynamics, and thus illustrate how useful such a modeling approach could be for ecological risk assessment.

**RA13D-5**

**Reviewing 15 years of European risk assessment: what if we had used models to assess ecological effects?**

F de Laender[1], P van Sprang[2], FAM Verdonck[2], CR Janssen[1]
[1]Ghent University, GHENT, Belgium
[2]Arche Consulting, GHENT, Belgium

Ecological effect assessments estimate threshold concentrations of chemicals that do not result in adverse effects on ecosystems. Two types of models that use single species effect concentrations (ECs) have been proposed to assist in such assessments: species sensitivity distributions (SSDs) and food web models. Here, we review the risk assessments of 123 existing chemicals evaluated between 1996 and 2009 to examine if SSDs and food web models could have been useful in obtaining ecological threshold concentrations for these chemicals. From the 123 chemical we considered, an effect assessment could only be performed for 77 chemicals, largely because of inadequate data availability. Median hazardous concentrations for 5% of the species (HC5) estimated by the food web model were better predictors of community NOECs measured in micro- and mesocosms than HC5s produced by SSDs, although community NOECs were only available for 9 out of 77 chemicals. Precision, quantified as inverse of the 90% confidence interval (CI) of the HC5s, could only be compared between both modelling approaches for chemicals with > 10 ECs available as significant SSDs could not be constructed for chemicals with less data. Precision of the food web model decreased with increasing sample size (from 1 to 10 ECs) but remained relatively constant at sample sizes > 10, at which it was comparable to that of chronic SSDs.

**RA13D-6**

**Microsporidia parasites in Gammarid: a confounding factor in the evaluation of cadmium toxicity**

E Gismondi[1], JN Beisel[1], T Rigaud[2], C Cossu-Leguille[1]
[1]LIEBE, METZ, France
[2]Equipe Ecologie Evolutive, UMR CNRS 5561, Biogeosciences, DIJON, France

Microsporidia are obligate intracellular parasites thought to be closely related to fungi. They are infecting a wide range of hosts inhabiting several environments (freshwater, marine or terrestrial). Microsporidia may use horizontal and/or vertical transmissions. Vertically-transmitted parasites are common in freshwater amphipods, where they can reach high prevalence and have several effects on host sexuality and behaviour. Because of their ubiquity and their obligate parasitic status, they are supposed to disrupt physiology of their host, but curiously, few studies have been devoted to search for the effects of parasite on energy reserves and how they interact with the antitoxic defence capacities of their host. Here, we investigated how parasites of Gammarus roeseli affect total lipid and glycogen contents, in parallel with reduced glutathione concentration, γ-glutamylcystein ligase activity and metallothionein concentrations as defence capacities. Toxic effects were highlighted by means of malondialdehyde measured as a biomarker of toxic effect. This study was carried out in physiological conditions and after cadmium exposure in laboratory conditions.
Two microsporidia species were detected in G. roeseli: Dictyocoela roeselum (prevalence = 68%) and Dictyocoela muelleri (32%). No male was infected while 72% of females harboured one of the two parasite species. In physiological conditions, there was no significant difference between uninfected and infected females for the different parameters, except for metallothionein concentration which was significantly higher in D. roeselum-infected females. After the exposure for 96 hours at two concentrations of cadmium (2 µg Cd.L-1 and 8 µg Cd.L-1), differences in energy reserves and antitoxic responses were observed between microsporidia-infected females and uninfected ones. The general observed pattern is that infection by microsporidia led to a larger antitoxic defence mobilization, as if the presence of parasites in the host cytoplasm (a biological "toxic") acted in synergy with the chemical toxic. Therefore, the detrimental effect of these parasites on host condition was evidence only under additional stress (here the cadmium pressure). More practically, this study highlights the necessary to take into account parasitological infections in ecotoxicological studies.

## RA14 - Waste fluxes around the world and the associated risks

**RA14-1**

**Environmental and health risks of chemical additives and recycling materials**

V Grundmann, B Bilitewski
Technische Universität Dresden, PIRNA, Germany

1. Introduction
Products undergo a recycling process and make their ways into a recovered material with unpredictable and not foreseen health and safety problems. The primary aim of RISKCYCLE is to identify future R&D needs required to establish a risk-based assessment methodology for chemicals and products that will help reduce animal testing while ensuring the development of new chemicals and product management pattern leading to minimized risks for health and the environment. The project is focussing on consequences due to the behaviour of chemicals and their release during recycling of the six fractions: paper, electronics, leather, lubricants, plastics, textiles.
2. Specific objectives of the project RISKCYCLE
The global trade of chemicals and products containing chemical additives such as paint, cosmetics, household cleaners, paper and cardboard, plastic toys, textiles, electronic appliances, petrol, lubricants etc. has resulted in a substantial release of harmful substances to the environment with risk to man and nature on a worldwide scale. Unpredictable and not foreseen health and safety risks due to recycling processes of products, which make their ways into a recovered material, are major issues of today`s waste management.
In spite of some common efforts to harmonize the safety assessment of chemicals and products a new problem with Recovered Material. The new threat is coming from closing the loop in a global scale. Plastic, paper and cardboard, lubricants and other products undergo a recycling process and make their ways into a recovered material with unpredictable and not foreseen health and safety problems.
The critical points throughout the products life cycle for the release of chemical substances and the hazardousness of the material set free will be evaluated. Beyond this it is also important to know if the effects caused by the chemicals have a global or only local meaning and if the release

of specific substances in the circular economy is an actual risk or a perceived risk.
Within the project the following key pieces of information will be required and collected: where are critical points throughout the products life cycle (for the release of chemical substances), how hazardous and toxic is the material set free, effects caused by the chemicals (global or regional meaning), risk (actual or perceived) of the release of specific substances in the circular economy.

**Review of models used for human health and environmental risk assessment**

J Rovira[1], M Mari[1], M Nadal[1], S Schuhmacher[1], JL Domingo[1], RM Darbra[2], A Àgueda[2], J Casal[2], E Capri[3], T Tanaku[3], A Ginebreda[4], D Guillén[4], D Barceló[4]
[1]Universitat Rovira i Virgili, TARRAGONA, Spain
[2]Universitat Politècnica de Catalunya, BARCELONA, Spain
[3]Università Cattolica del Sacro Cuore, PIACENZA, Italy
[4]IDAEA-CSIC, BARCELONA, Spain

The coordination action RISKCYCLE aims at establishing and coordinating a global network of international experts and stakeholders to define together future needs of R+D contributions for innovations in the risk-based management of chemicals and products in a circular economy of global scale. RISKCYCLE is focused on the fate and behaviour of additives used in six industrial sectors (textile, electronics, plastics, leather, paper and lubricants). Some of these additives are nonylphenoxy acetic acid, polybrominated diphenylethers, hexabromocyclododecane and triclosan, among others.
The goal of risk assessment of a chemical emission is to evaluate if the risk to any receptor (environmental compartment, population, individual) will be acceptable or not. For the last twenty years different models and methods have been developed to predict the impact of a chemical released into the environment in the context of risk assessment. Within the framework of RISKCYCLE project, a selection of risk assessment models has been done. The analysed models have been Ecopoints, ECOSENSE, EDIP method, Eco-indicator 99, USES-LCA/EUSES, Caltox, GLOBOX and USEtox, among others. Their weaknesses and the strengths have been analysed.

**RA14-3**

**Life cycle assessment and additives: state of knowledge**

HF Larsen[1], E von der Voet[2], L van Oers[2], Y Gao[3], T Rydberg[4]
[1]Technical University of Denmark, LYNGBY, Denmark
[2]CML, LEIDEN, The Netherlands
[3]Hefei University of Technology, HEFEI, ANHUI, China
[4]IVL, GOTHENBURG, Sweden

Concerns about possible toxic effects from additives/impurities accumulated in globally recycled waste/resources like paper and plastics was one of the main reasons for starting up the EU FP7 Coordination Action project RiskCycle (www.wadef.com/projects/riskcycle). A key aim of the project is to identify research needs within this area focusing on both risk assessment (RA) and life cycle assessment (LCA). Besides the sectors on paper and plastics also lubricants, textiles, electronics and leather are included in RiskCycle. On plastics a literature review regarding the state of knowledge on additives/impurities in LCA has been performed within RiskCycle. Several inventory databases (LCI data) have been investigated and the result shows that most LCI databases use PlasticsEurope data for plastics production. Most of these data are aggregated and do not include additives. Regarding the production of additives only data on metals and DEHP was identified. As regards LCAs on plastics 110 papers has been reviewed. Only 25 of these mention additives but they are not included in the emissions list. Only a few studies include additives in the impact assessment and additives are never mentioned as important for the outcome. Regarding LCAs on printed matter (including paper) only a few studies have been done - mostly focusing on the energy part. However, one of the most recent and comprehensive studies actually include toxic impacts from chemical emissions - mostly printing chemicals like printing ink of which some components may accumulate in recycled paper. Even though recycling is included in this recent study there is no special focus on the additives/impurities in the recycled paper. Anyway, the study shows that potential toxic impacts from the production and use of chemicals like pigments, solvents, metals, AOX and biocides may play a very significant role in the impact profile of printed matter. Regarding the life cycle impact assessment (LCIA) part an investigation of the availability of characterisation factors (aquatic ecotox) for the about 17 additives/impurities to be included in RiskCycle have been done. These additives belong to 15 chemical groups/chemicals like PFOS, PFOA, NPAA, HBCDD, triclosan and more. The best practice LCIA "consensus"model USEtox was chosen. For only nine of the 17 substances characterisation factors exists and four of these are preliminary (interim). Regarding the rest, factors have to be calculated - if possible.

**RA14-4**

**Occurrence assessment of PFCs in food, drinking water and biological human samples in Spain, and global comparison**

M Farre, ML Llorca, FP Perez, DB Barcelo
IDAEA-CSIC, BARCELONA, Spain

Perfluorinated compounds (PFCs) comprise a large group of compounds widely used in industrial applications that are characterized by a fully fluorinated hydrophobic linear carbon chain attached to one or more hydrophilic head. PFCs repel both water and oil, and are therefore ideal chemicals for surface treatments. PFCs have been manufactured for more than 60 years, and released into the environment following production and use. Two of the most important PFCs are perfluorooctane sulphonate (PFOS) salts, components of fire-fighting foam concentrates, and perflorooctane acid (PFOA), primarily used as emulsifier in industrial applications.
PFCs are ubiquitous environmental contaminants, which persist and may bioaccumulate through the food chain. These compounds have been detected worldwide in sediments and biota. In recent years, an increasing number of papers report high levels of PFCs in blood, tissues, and breast milk from both occupationally and non-occupationally exposed human populations.
The most important exposure pathways of perfluorinated compounds for humans are thought to be intake of drinking water, food and inhalation of dust. Due to the widespread distribution, environmental degradation, and metabolism of the PFCs released into the environment, a very complex exposure situation exists. As a result, the relative contribution to human exposure from different routes or from a single source is not yet known. Because of their bioaccumulation and potential health concerns including toxicity, and their possible contribution to cancer promotion, non-governmental organizations, national and international authorities have addressed the PFCs problem by several pressure and legislative actions.
This communication will present the concentration levels of 18 PFCs different type of matrices including drinking water and food, as well as, the levels encountered in breast milk, urine, cord blood and hair of donors from Spain. The analytical techniques used for their analysis along different studies performed by our group will be presented. Finally, results of exposure and human bioaccumulation in Spain will be compared at global scale by comparison with results reported worldwide. Relations between occurrence levels and ambient factors, drinking water pollution and type of diet will be as well discussed.

**RA14-5**

**Toxprint: an easy tool to translate process mass flow into toxicological impact**

D Baderna, SB Bordonali, EB Boriani, AC Colombo, SM Maggioni, EB Benfenati, ML Lodi
Mario Negri Institute for Pharmacological Research, MILAN, Italy

In the last years, an huge number of techniques has been developed to estimate the possible adverse effects on human health and ecosystems induced by the release of chemicals by human activities, in particular incinerators, landfills and industrial plants. The most important and spread techniques are human risk assessment (HRA), ecological risk assessment (ERA) and Life Cycle Assessment (LCA). HRA and ERA evaluate the induced risk accounting of the direct exposure of targets while LCA, instead, assess each impact associated with all the stages of a process. These tools are often very difficult to perform and require time to form experts and to perform the analysis. In order to save money and time, we are proposing Toxprint, an easy way to evaluate the toxicological impact of plant processes using data on their mass flow and their chemical characterization. Toxprint is a simplified tool that integrate the mass flow of a process, its toxicological and ecotoxicological analysis and the environmental fate of the chemicals characterizing the process. From the analysis of process mass flow, some compounds are selected as indicators of the entire process based on their toxicological profiles, environmental properties and quantity. For each chosen indicators, the Equivalent of Toxicity (ET) will be defined, depending on the nature of the compound (toxic or cancerogenic chemical). The Index of Toxicological Impact (ITI) and the Index of Ecotoxicological Impact (IEI) are then calculate for each compound as ratio between the quantity of compound and its ET or PNEC, respectively. The Environmental Fate and Transport (EFI) analysis of the compound is based on its water solubility, mobility, volatility, bioconcentration factor and persistence. The Toxprint of each indicator is calculated by the formula Toxprint_compound= (ITI+IEI)[GREEKX]EFI and, finally, the Toxprint of the process is estimated adding the single toxprint of compounds.
The integrated approach is applied to the leachate of a landfill in the Northern Italy which was subject of a 10-years monitoring program performed by our laboratory. Thirteen chemicals were selected as indicators due to their abundance and their frequency of finding, including heavy metals, phenols and other organic compounds. For the investigated site, the most concerning leachate components are copper and iron.
The proposed tool was partly founded by the EU project RISKCYCLE and Italian project FIRB.

**RA14-6**

**Application of an integrated approach to evaluate health risks for toxic chemicals by linking multimedia environmental and PBPK models**

T Tanaka[1], C Brochot[2], E Capri[3], N Suciu[3], E Johansson[4], P Ciffroy[5]
[1]INERIS, Verneuil en Halatte, France
[2]Institut National de l'Environnement Industriel et des Risques, VERNEUIL EN HALATTE, France
[3]Università Cattolica del Sacro Cuore, PIACENZA, Italy
[4]Facilia AB, BROMMA, Sweden
[5]EDF, Division Recherche et Développement, CHATOU, France

The paradigm of health risk assessment may consist of two main pillars, i.e., the exposure and dose-response assessments. Human exposure to chemicals via multiple pathways can be estimated by environmental multimedia models, which calculate the distribution of chemicals in the component media, i.e., air, water, soil, plants, and animal media. Combined with the information about human behaviors such as dietary habits, time spent outside, and etc, the multimedia models can provide an estimation of the daily chemical intake by inhalation or ingestion by humans. Physiologically based pharmacokinetic (PBPK) models are used to estimate the body burden of toxic chemicals throughout the entire human lifespan, integrating the evolution of the physiology and anatomy from childhood to advanced aged. The use of such PBPK models overcomes the limitations that dose-response modelling holds, e.g., it simply determines the relationship between the dose and the probability of an effect.
The European project 2-FUN (Full-chain and UNcertainty Approaches for Assessing Health Risks in FUture ENvironmental Scenarios) aims at improving the approaches currently used in exposure and dose-response assessments. According to the aim of that project, an environmental multimedia model and a generic PBPK model are coupled as an integrated tool (2-FUN tool) and built up on a platform system, Ecolego®. This study presents here the first application of the integrated tool to perform the full-chain risk assessment of a chemical for human health, considering multiple exposure pathways of chemical via inhalation of out-door air, and ingestion of water and foods. For this application of the tool, a case study was designed based on the information available in a region situated on the Seine river watershed, downstream of the Paris megacity and Benzo(a)pyrene (B(a)P) was selected as a target chemical substance. This study focuses especially on the propagation of uncertainty and inter-individual variability along the modelling chain. A probabilistic simulation was then performed to identify the input parameters and exposure pathways sensitive to model outputs (e.g., internal effective concentrations in organs).

## EC01 - Advances in passive sampling and dosing techniques

**MO 002**

**Passive sampling for the monitoring of organic pollutants (PAHs, BTEX) in groundwater. Application to a former industrial site.**

C Berho, AT Togola, BG Girardeau, LA Amalric, AS Saada
BRGM, ORLEANS CEDEX 02, France

Classical techniques for groundwater sampling can affect the measurement of chemical composition of water. Sampling devices such as low-flow peristaltic pumps can sample water slowly from wells to obtain representative samples but can also involve sorption of hydrophobic compounds to the tubing and losses of volatile compounds through volatilization. In this context, passive sampling technology presents several advantages associated with a low perturbation of the sample, including simplicity, low cost, no power requirement and possible estimation of time weighted average (TWA) concentration of pollutants.
The aim of this work is to present results obtained with two passive sampling devices, an integrative passive sampler (SPMD - Semi Permeable Membrane Devices) and an equilibrium passive sampler (PDBs -Passive Diffusion Bags) for respectively the estimation of PAHs and BTEX concentrations in groundwater at a former industrial site. Results were compared with those from classical analysis (LC/UV/fluorescence and ITEX/GC/MS for PAHs and BTEX respectively) on water samples obtained with a discrete interval sampler. The discrete sampler allows sampling with minimal disturbance of the water in comparison with classical sampling. SPMD were deployed for several time durations to estimate the kinetic accumulation of compounds. PDBs were deployed to estimate the BTEX concentrations in groundwater. First results demonstrated that BTEX concentrations in PDBs samplers were in good agreement with those estimated in water samples with the discrete interval sampler. This demonstrates that PDBs can estimate the VOC concentrations in the well at a defined depth. For most of PAHs, the kinetic accumulation was linear over the deployment period. For some PAHs, time average concentrations (TWA) estimated with SPMD could be in good agreement with those found in water samples.
Acknowledgement - The authors thank ADEME (French Environment and Energy Management Agency, ATTENA Project) and the research division of BRGM (ECHANT ES project) for their financial support.

**MO 003**

**Applicability of passive sampling to groundwater monitoring**

C Berho, AT Togola, JPG Ghestem
BRGM, ORLEANS CEDEX 02, France

Passive sampling technology has become of great importance in the field of environmental monitoring for several years, due to its well-known advantages (low perturbation of the sample, time weighted average concentration estimation [3DOTS]). Although passive samplers have been successfully used in a variety of field studies in surface waters, only a few studies have tested their applicability in groundwater. Indeed, groundwater presents specificity such as a low velocity of water which might affect the uptake of compounds in passive samplers. Moreover, the use of passive samplers in groundwater supposes the water in the well to be representative of the whole groundwater.
The aim of this work is to test several passive sampling devices (DGT, POCIS, PDBs) for the monitoring of metals, pesticides, and volatile organic compounds (VOC) in groundwater in order to identify the pros and cons of this technique for groundwater applications. Several campaigns of measurements were conducted in order to compare the results obtained by passive sampling with those obtained by classical sampling. All passive samplers were deployed in replicates in a well and at different depths to study the stratification of pollutants. First results demonstrated that:
- A good repeatability is observed on the passive sampling results,
- VOC concentrations obtained by PDBs are in accordance with those obtained by classical sampling in the well. These results highlighted that PDBs allow the measurement of the VOC concentrations at different depths easily,
- In some cases, the low water velocity seems to limit the uptake of compounds for integrative passive samplers. This factor has thus to be taken into account for the calculation of the concentration in water.
Acknowledgement - The authors thank ONEMA via AQUAREF and the research division of BRGM (ECHANT ES project) for their financial support.

**MO 004**

**Occurrence and fate of pesticides in Arcachon's bay using the passive sampler approach**

AW Belles[1], N Tapie[1], V Fauvelle[2], N Mazzela[2], H Budzinski[1]
[1]LPTC, TALENCE, France
[2]CEMAGREF, CESTAS, France

Conventional water sampling techniques are time consuming and cost effective, especially when heavy logistical organisation is required to assure a high frequency sampling that is necessary to take into account the variability occurring in pollutant contamination.
Indeed, the chemical characterisation of coastal waters and of transition water systems such as estuaries or bays is complex because important dilutions and important temporal variability usually occur. To overcome the problem posed by the temporal variability of the water concentration, various passive sampling techniques were developed allowing the estimation of the mean water concentration of the pollutants over the exposure time.
The present work thus aims to evaluate the presence and the sources of pesticides in the Arcachon Bay (South West coast of France). Various environmental problems have occurred these last few years in this quite complex and vulnerable ecosystem with regression of sea grass, alteration of oyster physiological condition... In view to understand the potential role of chemical contamination on these phenomena, water bay contamination was monitored. Indeed among all the potential parameters that can affect water quality, chemical contamination is crucial to document and among all the potential suspected contaminants, pesticides can play a significant role. To evaluate pesticide sources and to precisely characterize their presence, antifouling and various herbicides were monitored in the main tributaries and in also directly in Arcachon Bay by discrete and passive samplings. Both types of sampling were compared. Furthermore tributary contribution to the Bay contamination was evaluated.

**Improvement and application of the polar organic compound integrative samplers (POCIS) using Performance reference compound approach for pesticides and pharmaceutical substances**

AW Belles, N Tapie, H Budzinski
LPTC, TALENCE, France

Since few years, the application of POCIS to monitor hydrophilic compounds in dissolved medium is commonly used. Unfortunately, the sampling rates of these tools are affected by several environmental parameters like hydrodynamic conditions, temperature and bio-fouling. Consequently, the sampling rates calculated in laboratory experiments are not adapted for the majority of environmental assessments. To overcome this phenomenon, the performance reference compound approach was developed during the 90's for the Semi Permeable Membrane Devices (Prest et al. 1997) and the same approach was later adapted to the POCIS tools for the pesticides using the Desisopropyl Atrazine d5 as reference compound (Mazzela et al. 2007/2010).
The PRCs are put into the receiving phase of the sampler before the exposure. During the exposure, the PRCs are eliminated from the receiving phase. Their elimination rates allow to determine the specific sampling rates of target analytes in the in situ condition.
In this study the PRC approach was developed for the pharmaceutical pollutants sampled by POCIS. A first experiment was performed to determine the pharmaceutical compounds which can be used as PRC, among which the Caffein C13, Salbutamol d3 present a satisfactory behaviour. In a second time, a laboratory experiment was realised to calibrate the previous PRCs and the Desisopropyl Atrazine d5. Simultaneously the sampling rates of pesticides and pharmaceutical compounds were evaluated . Finally, the devices were exposed in the Gironde estuary during one year to evaluate the pesticide and pharmaceutical contamination of this ecosystem.

**Pesticide monitoring of Arcachon bay using various passive sampling techniques**

AW Belles, N Tapie, H Budzinski
LPTC, TALENCE, France

The present work focuses on the study of the pesticide contamination of the Arcachon bay in the south west coast of France. This hydrological system is extensively used for a large number of activities (fishing, agriculture, tourism). In addition, many tributaries which receive drainage and runoff waters from the surrounding irrigated fields of various cultivated areas contribute to the water bay potential contamination. In this context, and since few years, several research programs have investigated the water contamination to evaluate pesticides pressure on this ecosystem. For this purpose, the passive sampling approach was frequently used to assess the global contamination of the water bay since it overcomes drawbacks of spot sampling approach which gives only the contamination at the time of sampling and not at all integrated assessment of it..
In this study, the monitoring of the water bay pesticide contamination was completed using simultaneously the grab sampling and passive sampling approach during one year.
Three types of passive samplers were used : The Silicon rubber samplers which can trap the most hydrophobic pesticides, the polar organic integrative samplers (POCIS), and an adaptation of the classical POCIS which are made with a highly porous membrane to reduce the mass transfer resistance and improve the detection limit of this tool. These three passive samplers exposed in the same environmental medium allow to evaluate the performance of each, their advantages and drawbacks for various compounds present in the water of the bay.

**Screening for Stockholm Convention POPs in Bosnia and Herzegovina using passive methods**

C Harman[1], M Grung[1], E Fjeld[1], S Rognerud[1], SB Ranneklev[1], M Sober[2], J Djedjibegovic[2], A Marjanovic[2], K Sinanovic[2], T Larssen[1]
[1]Norwegian Institute for Water Research, OSLO, Norway
[2]University of Sarajevo, SARAJEVO, Bosnia-Herzegovina

In contrast to the significant quantity of information available regarding the occurrence of persistent organic pollutants (POPs) in the European Union (EU), there is a paucity of data concerning concentrations of such compounds in Bosnia and Herzegovina (BiH). Additionally BiH has just recently signed and ratified the Stockholm convention, although its implementation hasn't started yet largely due to the country's complex socio-political situation. In an attempt to improve this we have carried out a suite of screening studies in BiH during the period 2007-2011. Two of the primary aims of these projects are capacity building for regular environmental monitoring and the identification of point sources and compounds of concern. In this regard the use of passive sampling devices (PSDs) is an advantageous approach allowing, unattended time integrated measurements, low detection limits and relatively inexpensive and straightforward laboratory procedures. In the present work we present data from several studies where semipermeable membrane devices (SPMDs) were deployed in two major rivers; the Neretva and the Bosna. Target compounds included polychlorinated biphenyls (PCBs), polycyclic aromatic hydrocarbons (PAHs), organochlorine pesticides (OCPs), and polybrominated diphenyl ethers (PBDEs). Additionally we tested the applicability of cheaper low density polyethylene PSDs including the use of fluorinated PAH (F-PAH) as performance reference compounds and briefly compared concentrations to those found in locally caught fish and large volume water samples with extraction by polyurethane foam (PUF). Levels of POPs were generally in the low pg L-1 range, with a clear gradient in exposure shown downstream in the Neretva River with higher and more variable concentrations found in the more industrially influenced Bosna River. Similar to previous results LDPE accumulations compared well to those of SPMDs where deployment equipment, surface areas etc. were similar. Differences between PSDs and the other matrices examined are discussed in terms of their chemical and phase selectivity and of their suitability for addressing the aims of the project.

**Combining passive sampling (PSII herbicides) and remote sensing (water quality) data on the Great Barrier Reef, Australia**

E Kennedy[1], T Schroeder[2], C Bentley[1], KL Chue[1], C Paxman[1], P Thai[1], V Brando[2], A Dekker[2], JF Mueller[1]
[1]The National Research Centre for Environmental Toxicology, BRISBANE, Australia
[2]CSIRO, BRISBANE, Australia

The Reef Rescue Marine Monitoring Program (MMP) was established to assess any change in water quality on the World Heritage Area Great Barrier Reef (GBR). Annual monitoring of the concentrations of photosystem II inhibiting (PSII) herbicides such as diuron, atrazine, hexazinone and tebuthiuron has been conducted at inshore reef sites along the GBR for up to five years using passive sampling techniques. As a result of this a unique set of data is now available that provide seasonal and regional trends of monthly or bimonthly average concentration estimates of these chemicals in the water column at these sites. In addition to pesticide monitoring at relatively few sites, remote sensing has been used to provide high spatial resolution data on the concentrations of water quality parameters (total suspended sediment, chlorophyll-a and coloured dissolved organic matter). One of the dominant contributors to declining water quality within the GBR are terrestrial discharge derived inputs of elevated nutrients, sediments and agricultural chemicals from adjacent catchments. There is some evidence for synergistic effects between specific water quality parameters and PSII herbicide concentrations on crustose coralline algae which may influence the structure and functioning of coral reefs. The aim of this work is to provide a preliminary evaluation of the statistical relationships between remote sensing derived water quality parameters and the concentrations of specific PSII herbicides on the GBR. The information gained from this work may be used to inform research into the effects of multiple stressors such as a decline in water qualtiy and exposure to PSII herbicides, on reef ecosystems. Furthermore it may eventually provide a tool that can be used for predictive purposes and to evaluate whether changes in pesticide usage and/or land management results in future differences in the observed relationships at these specific locations.

**Comparison between in situ Stir Bar Sorptive Extraction and the Polar Organic Chemical Integrative Sampler for the passive sampling of agricultural pesticides**

A Assoumani, S Lissalde, C Guillemain, C Margoum, N Mazzella, M Coquery
Cemagref, LYON, France

The monitoring of organic micropollutant contamination in water bodies and the determination of reliable concentration estimates have become challenging issues in Europe, since the Water Framework Directive (WFD, European Commission, 2000) has aimed to improve and protect european rivers by 2015. For the determination of the concentrations of micropollutants such as pesticides, several sampling techniques can be employed. The pertinance of grab sampling can be questionable in case of temporal variations of these concentrations in rivers, when it is performed at low frequencies. Automated or active sampling allows more reliable estimates of the contamination because averaged samples can be taken over a large time period. Nevertheless, this technique is often time-consuming and expensive for the purchase, as well as for the utilization and the maintenance. Integrative or passing sampling has recently been developped in order to obtained, at lower cost, realistic estimates of the contamination levels of the aquatic environment. The polar organic chemical integrative sampler (POCIS) is one of the main devices used for the passive sampling of the moderately polar organic compounds. Its efficiency in the determination of time-weighted average concentrations of hydrophilic pesticides has been reported in the literature. Stir bar sorptive extraction (SBSE) is a solvent free sample preparation technique dedicated to organic compounds in aqueous samples. It is composed of a magnet enclosed in a glass tube coated with a thick film of polydimethylsiloxane (PDMS). The *in situ* application of this technique has also been reported in the literature.

Stir bars and POCIS were deployed for two weeks in two rivers of a french agricultural watershed. The aim of this study was to assess the performances of the SBSE applied *in situ*, and to compare them with the POCIS results, regarding the passive sampling of agricultural pesticides in surface waters. Good repeatability and sensitivity of the *in situ* SBSE have been obtained for the hydrophobic pesticides, and increasing concentrations of micropollutants have been determined from the up-stream to the down-stream of the rivers sampled. Differences in the nature and the amount of the target compounds accumulated on the two sampling devices have allowed the authors to suggest the SBSE as a complementary passive sampling technique for the monitoring of more hydrophobic pesticides in the aquatic environment.

**Affinity of Chemcatcher's receiving phase for polar herbicides sampling**

II Ibrahim[1], GC Gonzalez[2], AT Togola[3], RG Greenwood[4]
[1]ECOLE DES MINES D'ALES, BRGM, ALES, France
[2]ECOLE DES MINES D'ALES, ALES, France
[3]BRGM, ORLEANS, France
[4]School of biological Sciences, University of Portsmouth, PORTSMOUTH, United Kingdom

The occurrence of agrochemicals in water resources requires a regular monitoring for water quality. The conventional method used for monitoring relies on discontinuous spot sampling at fixed time intervals. However this method is not an efficient way to assess periodic fluctuations of pollutants concentration. Throughout the last decades, an alternative sampling technique called passive sampling has been used successfully for various pollutants monitoring in aquatic environments. Passive samplers represent a promising alternative to grab sampling as they continuously accumulate dissolved organic pollutants from water and allow the measurement of time weighted average (TWA) concentrations.

Different types of samplers are commercially available among which we focused on Chemcatchers®. It consists of a polytetrafluoroethylene sampler body in which different solid phase materials and diffusion membranes can be incorporated in order to optimize the accumulation of a wider set of target compounds. This accumulation depends on diffusion mechanisms, particularly into the receiving phase.

The presented work addresses the topic of polar herbicides occurring on different aquatic compartments (surface and groundwater for example). The objective is to select the most appropriate receiving phase with the higher affinity for the studied target pollutants. Thus, we compared the efficiency of different solid materials as receiving phase (Empore© disks) incorporated into Chemcatchers®. Devices were exposed to aqueous solutions containing the selected herbicides in order to evaluate kinetic accumulation of analytes. This work focuses on the comparison of kinetic constants and total mass analytes accumulated on each Empore© disk (as for example C18, SDB-XC, SDB-RPS).

Based on this study, a Chemcatchers® calibration step, at laboratory scale, could be carried out with the selected receiving phase in order to estimate the sampling rates (Rs) of pollutants. This calibration is necessary prior to use Chemcatchers® for field studies (water monitoring).

**Determining pesticide uptake rates for the polar organic chemical integrated sampler using field data**

T Gallé, M Bayerle, D Pittois
CRP Henri Tudor, ESCH-SUR-ALZETTE, Luxembourg

A crucial issue in using passive sampling techniques like the polar organic chemical integrated sampler (POCIS) for environmental monitoring of pesticides and pharmaceuticals is the determination of reliable uptake rates. Often uptake rates are determined under lab conditions not reflecting natural conditions. Knowing that turbulence, temperature, salinity and biofouling can have an impact on the uptake rates of passive sampling devices, calculations of water concentrations using only lab-derived uptake data might be heavily biased. Therefore, auto sampler campaigns have been run in parallel to POCIS deployments in four Luxembourgish sewage treatment plant effluents as well as their receiving rivers during 24 hours. Substance specific uptake rates have been calculated by using data of the POCIS extracts and results of the auto sampler campaign analyzed via LC-MS/MS. It can be shown that these "field-derived"-Rs-data are between the values obtained during the calibration in the lab. The latter values showed large variations and were strongly dependent on the stirring i.e. on the turbulence of the system during the experiment. Therefore, a sound determination of the time weighted average concentrations for the investigated compounds should be based on uptake rates, which have been verified on-site. In the same study, POCIS also have been exposed during 14 days at the same sites as a witness of the pesticides' presence during and between the grab sampling. It turns out that the limits of detection for POCIS are in the range of 1 ng/l for most of the 20 monitored substances. Therefore, the use of passive samplers can improve the limits of quantification by one order of magnitude compared to the measurement of grab samples. Using on-site verified sampling rates, POCIS allow for an integrative monitoring down to the trace level. Within the 14 day sampling period, even more substances could be detected than have been found in the 24 hour samplings. This combined approach with 24 hour and 14 day deployment of POCIS also allows for a rough calculation of the variation and possible contamination peaks during the investigated period.

**Laboratory calibration of POCIS: kinetic accumulation of 59 polar organic contaminants and evaluation of candidate performance reference compounds**

NA Morin[1], J Camilleri[2], C Cren[2], M Coquery[1], C Miège[1]
[1]Cemagref, LYON, France
[2]Service Central d'Analyses (SCA) du CNRS, SOLAIZE, France

POCIS (Polar Organic Chemical Integrative Sampler) is a new emerging tool for sampling polar organic micropollutants in water (Alvarez et al., 2004). It is still in development concerning its domain of validity (e.g. molecules sampled, type of water studied, optimal exposure duration) and its performances, including the definition of molecules sampling rates, repeatability, accuracy of the evaluation of time-weighted average (TWA) concentrations. Performance reference compounds (PRCs) enable to decrease the effect of variable environmental conditions, so they can be used to obtain more reliable TWA concentrations in situ. To our knowledge, for POCIS, only one PRC has been identified to date: deisopropylatrazine-d5, that has been used and proved efficient for polar herbicides monitoring in freshwater (Mazzella et al., 2007, 2010).

In order to obtain in situ TWA contaminant concentrations, POCIS needs to be calibrated in laboratory for each molecule of interest. Our work was based on laboratory calibration of POCIS for 5 alkylphenols, 9 hormones, 12 pesticides, 29 pharmaceuticals, 3 phenols and 1 UV filter in a flow-through system. This system was composed of 2 aquaria (50 L) containing i) spiked tap water (circa 3 µg/L) and non-spiked POCIS for the determination of accumulation kinetics or ii) non-spiked tap water and spiked POCIS for the determination of desorption kinetics. In both experiments, water temperature, pH, conductivity and dissolved organic carbon were controlled. Agitation in the aquaria was ensured via a submerged pump. The resulting flow velocity was 10±5 cm/s and was directed perpendicularly towards POCIS surface. Triplicate POCIS were analyzed at 0, 1, 3, 6 and 12 hours and at 1, 3, 7, 11, 14, 21 and 28 days.

We will present various results depending of molecules such as the duration of linear accumulation phase and sampling rates, sampling repeatability and possible PRCs. As for example, linear accumulation phase for estrogenic hormones seems to be 21 days, since at 28 days the equilibrium regime begins to be reached. For betablockers, linear accumulation phase is shorter: less than 14 days. Sampling rates for this 2 families of compound vary from 0.058 L/d for sotalol to 0.537 L/d for 17-a-estradiol. Concerning the desorption experiments, atenolol-d7 and sotalol-d6 for example show a good potential as PRCs. Indeed, a desorption of 70% for atenolol-d7 and 50% for sotalol-d6 was observed in 24 days.

**A method for the in situ calibration of a passive phosphate sampler in estuarine and marine waters**

DS O'Brien[1], K Booij[2], DW Hawker[3], JF Mueller[1]
[1]The University of Queensland, BRISBANE, Australia
[2]Royal Netherlands Institute for Sea Research, TEXEL, The Netherlands
[3]Griffith University, BRISBANE, Australia

Passive samplers for phosphate were calibrated in the laboratory over a range of flow velocities (0-27 cm s 1) and ionic strengths (0-0.62 mol kg 1). The observed sampling rates were between 0.006 and 0.20 L d 1. An empirical model allowed the estimation of these sampling rates with a precision of 8.5%. Passive flow monitors (PFMs), based on gypsum dissolution rates, were calibrated for the same range of flow velocities and ionic strength. Mass loss rates of the PFMs increased with increasing ionic strength. We demonstrate that this increase is quantitatively accounted for by the increased gypsum solubility at higher ionic strengths. We provide a calculation scheme for these solubility's for an environmentally relevant range of temperatures and salinities. The results imply that co-deployed PFMs can be used for estimating the flow effect on the in situ sampling rates of the phosphate samplers, and we expect that the same may hold for other passive samplers.

**MO 014**

**Determination of deployment specific chemical uptake rates for SPMD and PDMS using a passive flow monitor (PFM)**

DS O'Brien[1], T Komarova[2], JF Mueller[1]
[1]The University of Queensland, BRISBANE, Australia
[2]Queensland Health Forensic and Scientific Services (Inorganics)., BRISBANE, Australia

Monitoring of micro-pollutants in the aquatic environment remains a challenge. In the last decade passive sampling techniques have been developed that facilitate the time integrated monitoring of target chemicals through the use of selective receiving phases. These techniques rely on the implementation of methods that will negate the effects of environmental factors (such as flow, temperature, etc.) or that will facilitate the quantitation of site and chemical specific rates of uptake into the passive sampler employed. This uptake follows first order, linear kinetics when either an ad- or ab- sorbent is employed as a receiving phase. The use of performance reference compounds (PRCs) has been established for the in-field calibration of passive samplers when the target analyte is absorbed. We have adopted an in situ calibration technique based on the dissolution of gypsum to measure the average water velocity a sampler has been exposed to. We have demonstrated that the loss of gypsum from the passive flow monitor (PFM) can be applied to predict changes in Rs dependant on flow when using the absorbent SPMD (semipermeable membrane device) or PDMS (polydimethyl siloxan) passive samplers. The study further demonstrates the applicability of the PFM in situ calibration method when quantifying the effect of flow/turbulence on chemical specific uptake kinetics. The application of this tool will enhance the accuracy when calculating and reporting environmental pollutant concentrations measured through the use of passive sampling devices.

**MO 015**

**The performance of Passive Flow Monitors and phosphate accumulating passive samplers when exposed to pulses in external water flow rate and/ or external phosphate concentrations**

DS O'Brien[1], DW Hawker[2], M Shaw[3], JF Mueller[1]
[1]The University of Queensland, BRISBANE, Australia
[2]Griffith University, BRISBANE, Australia
[3]Department of Environment and Resource Management, BRISBANE, Australia

Passive samplers are typically calibrated under constant flow and concentration conditions. This study assessed whether concentration and/or flow pulses could be integrated using a phosphate passive sampler (P-sampler). The assessment was conducted in three 21 day experiments featuring a pulse in flow rate, a pulse of Filterable Reactive Phosphate (FRP) concentration and a simultaneous concentration and flow rate pulse. FRP concentrations were also determined by parallel grab sampling and the P-sampler calibrated with Passive Flow Monitors (PFMs) and direct measurement of flow rates. The utility of PFMs as a flow-monitoring device with variable flow conditions was successfully demonstrated. Good agreement was observed between the grab and passive measurements of FRP concentration when exposed to a pulse in flow (6% overestimation) or concentration (2% underestimation). However, a 32% overestimation occurred with a simultaneous concentration and flow rate pulse. Results obtained were consistent with a lag time for accumulation within the P-sampler

**Atmospheric input of persistent organic pollutants into soils close to the urban Rhein-Main-Area (Germany)**

S Ambs[1], T Schiedek[2], S Weinbruch[3], C Schueth[2]
[1]Hessian Agency for Environment and Geology, WIESBADEN, Germany
[2]Technical University of Darmstadt, Institute of Applied Geosciences, DARMSTADT, Germany
[3]Technical University of Darmstadt, DARMSTADT, Germany

Persistent organic pollutants like Polycyclic Aromatic Hydrocarbons (PAH) are ubiquitous in the environment. PAH are mostly generated by incomplete combustion processes, i.e. urban emissions from traffic, industry and residential areas (particularly house heating in winter). Even in rural areas the enrichment of organic pollutants in soil is often dominated by atmospheric deposition Yet, only little is known on the impact of urban short-range PAH deposition and accumulation in soil.

The Rhein-Main region in Germany is one of the most densely populated and highly industrialized areas in Europe with the adjacent Taunus mountains (25 km W of Frankfurt) as one of the most probable receptors of urban emissions. The aim of the project was to investigate the impact and the seasonal variation of the short-range transport and deposition of PAH.

The atmospheric input at three test sites (urban influenced, mountain crest and rural) was investigated using passive samplers for particles (sigma2 samplers), air (PUF disks) and atmospheric bulk PAH deposition. A typical sampling period lasted 3 months. Furthermore, soil samples were analysed for PAH.

The aerosol composition as determined by environmental scanning electron microscope analyses (ESEM) revealed the urban impact on the urban exposed area and on the mountain crest. The rural test site showed a clearly different aerosol composition and thus lower urban impact. The fraction of sulfate particles, as a typical component of urban aerosol, decreased at the test sites from ca. 50% (urban) to below 5% (rural) within a distance of ca. 10 km.

Air and bulk deposition samples showed higher PAH deposition rates in winter at all test sites. While the air depositon rates were slightly higher at the mountain crest, the bulk PAH deposition was significantly higher at the urban site and on the mountain crest. These observations probably results from additional sources in winter (heating period) and decreased degradation. Soil samples from the mountain crest showed the highest PAH contents. Samples from low altitudes at the urban and the rural test side showed significantly lower but comparable PAH contents. This indicates that the mountain range is scavenging the persistent PAH. To evaluate the mass transfer of pollutants in the study areas, future work will focus on input-output balances and assessment of pollutant storage in soils.

**Air monitoring of POPs near a waste incineration plant. Suitability of air passive sampling devices.**

L Vilavert, M Nadal, M Mari, M Schuhmacher, JL Domingo
Rovira i Virgili University, REUS, Spain

High-volume active samplers are generally used as conventional sampling techniques for monitoring persistent organic pollutants (POPs) in air. The relatively high cost of this equipment, together with some technical requirements such us a pump and source electricity, are important disadvantages of these sampling methods. A potential alternative of high interest is the use of passive samplers. These devices allow semi-quantitative comparisons of the atmospheric POP levels. Taking into account their low cost and simple manipulation, polyurethane foam (PUF) disks are especially attractive. In recent years, the viability and suitability of using passive samplers, as a substitute of conventional systems, have been studied in Catalonia. Both techniques have been alternatively used to monitor the environmental impact of waste management plants (e.g., incinerators, landfills, etc.) by analyzing the levels of polychlorinated dibenzo-p-dioxins and dibenzofurans (PCDD/Fs). Between March and June 2010, 8 PUF devices were deployed at different sampling sites around the municipal solid waste incinerator (MSWI) of Tarragona (Catalonia, Spain). The airborne concentrations of PCDD/Fs, as well as polybrominated diphenyl ethers (PBDEs), polychlorinated biphenyls (PCBs) and polychlorinated naphthalenes (PCNs), were analyzed. Following the passive samplers theory, the sampling rate for the pollutants analyzed here was previously acquired from the scientific literature. The mean flow rate for the different PCDD/F congeners was approximately 2 m3/day, while that established for PBDEs, PCBs and PCNs was around 3 m3/day. The reported concentrations of PCDD/Fs in air ranged between 6.95 and 22.3 fg WHO-TEQ/m3. PBDE average level was 41.9 pg/m3, and PCN mean concentration was 3.10 pg/m3. Regarding PCBs, the concentration of dioxin-like congeners accounted for between 0.18 and 6.17 fg WHO-TEQ/m3, and the mean levels of the 7 environmental marker PCBs was 57.7 pg/m3. According to the results of all POPs in air samples, we can still consider that the MSWI does not have a significant impact on the area under its direct influence, with respect to the emissions of PCDD/Fs, PBDEs, PCBs and PCNs. The concentrations found here are similar or even lower than those values obtained in other studies conducted in areas near waste incinerators and other industrial/urban areas.

**MO 018**

**Concentrations of polychlorinated biphenyls (PCBs), polibrominated diphenyl ethers (PBDEs) and polycyclic aromatic hydrocarbons (PAHs) using passive air sampling in Tuscany region, Italy**

VH Estellano Schulze[1], KP Pozo[1], VV Volpi[1], TH Harner[2], PG Perra[1], SC Corsolini[1], FS Focardi[1]
[1]University of Siena, SIENA, Italy
[2]Meteorological Service of Canada, TORONTO, Canada

Passive air samplers consisting of polyurethane foam disk were deployed over a 3-month period from April to July 2008 at 19 locations throughout the Tuscany Region in central Italy. Sampling sites were selected based on different criteria including urban, rural and agricultural sites. The purpose of the study was to assess the gas-phase concentration of PCBs, PBDEs and PAHs on a local and regional scale. Derived air concentrations (pg/m3) ranged from below detection limit (BDL) to 304 (52 ± 98) for ∑6PCBs and from BDL to 104 (21 ± 34) for ∑8PBDEs. For PAHs the concentrations were much higher with values between 292 to 4670 pg/m3 (2051 ± 1316). The highest PCBs concentrations (pg/m3) were observed at urban sites, peaking at Piombino (304), follow by the rural sites at Fogliano Grosso (45). At the agricultural sites (Siena Nord, Montalcino, Val d'orcia, Abbadia San Salvatore and Arcidoso) the concentration were BDL for all the sites. The highest concentration of PBDEs was recorded at Scarlino (104 pg/m3), a rural site, though there were not big differences between the three categories. The highest level of PAHs was found at Siena Nord (4670 pg/m3), close to the Siena-Florence highway. The PCBs congeners composition frequently detected for PCBs included 28/31, 52, 99, 105, 118 and 149; the congeners with 5-cl were the predominant accounting for the 91%, followed by the 4-cl with 7%. For PBDEs the predominant congeners were 15, 49, 66 and 100. PAH with 3-6 benzene rings were analysed, the most abundant was 3 ring-congeners accounting for 76 ± 6 % of the total PAHs composition. Phenantrene alone accounted for the 45 ± 11 % of the total PAHs composition. The percentage for 4 rings and 5 ring-congeners was 24 ± 6 % and 0.1 ± 0.3 %, respectively. The concentration of PCBs and PBDEs showed a big variation between the different sites probably showing local emissions and highlighting localised hotspots. This study shows the feasibility of using PUF disks as time-integrated passive samplers, assessing local and regional scale for concentrations of POPs in central Italy.

**MO 019**

**Influence of passive air sampler configuration on chemical uptake by the sampling medium**

X Zhang[1], Y Lei[1], F Wania[1], M Tsurukawa[2], T Nakano[2]
[1]University of Toronto, TORONTO, Canada
[2]Hyogo Prefectural Institute of Environmental Sciences, KOBE, Japan

Passive air samplers (PASs) of various configurations have been widely applied to monitor semi-volatile organic compounds (SVOCs) in the atmosphere. Trying to understand how sampler design affects chemical uptake, we investigated different configurations of a PAS, which relies on cylindrical, sorbent-filled mesh cylinders as sampling medium. Silica-gel and XAD-2 were used to sample water vapor and SVOCs respectively. Water uptake by silica-gel was measured gravimetrically, which enables numerous replicated measurements in a short period. Experiment results show that the PAS sampling rate (R, m3/d) is (i) determined by the surface area of the sampling medium exposed to air, and (ii) influenced by the distance of the sampling medium to the opening of the PAS shelter. Due to their high molecular diffusivity, water molecules are expected to be uniformly distributed within the sampling medium. The experimental data on water uptake indeed conform well with a PAS uptake model that assumes uniform distribution. However, more and more evidence questions the validity of this assumption for the uptake of SVOCs in PAS. In order to test this assumption, experiments are being conducted to characterize the distributions of SVOCs within the two sampling media most commonly employed in PAS (polyurethane foam and XAD) by separately analyzing axially and radially segmented sampling media. Results indicate inhomogeneous axial distribution of PCBs within XAD-filled mesh cylinder at wind still conditions. Wind blowing towards the opening of a PAS shelter greatly increases R and tends to homogenize the axial PCB distribution within XAD-filled mesh cylinder.

**MO 020**

**Use of chemical probes and passive samplers for the determination of the atmospheric input and fate of persistent organic pollutants (POPs) in soil**

M Laxander[1], T Schiedek[1], S Ambs[2], C Schüth[1]
[1]TU Darmstadt - Institute for Applied Geosciences, DARMSTADT, Germany
[2]Hessisches Landesamt für Umwelt und Geologie, WIESBADEN, Germany

Persistent organic pollutants (POPs) such as polycyclic aromatic hydrocarbons (PAHs) and polychlorinated biphenyls (PCBs) can be found ubiquitously in the environment. They are typically emitted from local and/or diffuse sources and enter the atmosphere either in their gaseous form or sorbed to carbonaceous particles. Removal from the atmosphere is due to wet and dry deposition and this can lead to an accumulation of the POPs in soils and sediments. However, after deposition climate-controlled desorption and evaporation processes may lead to a contaminant remobilization. It was speculated that especially in high altitudes remobilized contaminants may accumulate and contaminant patterns may change, due to the contaminants chemical and physical properties. These processes are summarized as cold condensation or cold trapping. In our study we used PAHs and PCBs as model compounds to study climate and altitude triggered fractionation processes in detail. In two remote alpine valleys and in a valley in the Black Forest test sites were equipped to (i) quantify wet and dry deposition of these compounds using bulk deposition samplers and air samplers, and (ii) to determine evaporation rates using chemical probes. Measured deposition rates were two orders of magnitude higher for PAHs compared to PCBs. However, while higher deposition rates for PAHs were found in winter, presumably due to increased combustion in the heating period, PCB deposition rates were higher in summer, indicating increased evaporation from sources at higher temperatures. For the chemical probes, various sorbents were preloaded with selected PAHs and PCBs (several mg/kg), filled into mesoporous ceramic tubes and deployed at the test sites. After 9 months the tubes were collected and the sorbents analyzed for evaporative losses. Evaporation rates were found to correlate with vapour pressure and were negatively correlated with altitude. For quartz sand as the sorbent, losses of naphthalene and phenanthrene were close to 100%. For stronger sorbents, e.g. charcoal and peat, losses were much smaller and in some cases even an increase in loading was observed.

**PCBs levels in the atmosphere of industrial, urban and rural areas of the Rhine Valley: case**

**of Strasbourg (France) and Kehl (Germany)**

M Millet[1], FG Gueguen[2], PS Stille[1]
[1]University of Strasbourg / CNRS, STRASBOURG CEDEX, France
[2]LHyGeS (UMR 7515)/LMSPC (UMR 7515), STRASBOURG, France

Passive air samplers (PAS) with XAD-2 resin have been used to measure polychlorinated biphenyls PCBs concentration in the atmosphere. This study was performed in the Rhine Valley, in the urban environment of the cities of Strasbourg (France) and Kehl (Germany) close to an important industrial harbour and in a remote area. Main industries in the harbour zone are waste incinerators, a steel plant, a thermal power plant and a petrol harbour. 22 congeners were analyzed by GC-2ECD after extraction on accelerated solvent extraction (ASE) and purification on silica and acidified silica gel. More than 80 samples were collected between March 2009 and August 2010 with a collecting time period of 4 weeks, in the industrial harbour but also in the urban and remote areas. Mean PCB concentrations measured in industrial, urban and forested zone were 3.9 ng.PAS-1d-1 (n=21), 3.8 ng.PAS-1d-1 (n=18) and 1.3 ng.PAS-1d-1 (n=14), respectively. The similar proximity of Kehl and Strasbourg center to the industries explains the similar PCB concentrations. Spatial and temporal trends were observed. Background level was measured in a remote area in the Vosges Mountains: concentrations were low in April-September: 0.9 ng.PAS-1d-1 and higher in October-March period 1.9 ng.PAS-1d-1. Similar concentration profiles were measured at different sites in the urban or rural areas. Two particular events were measured in April 2009 and February-March 2010 with the highest concentration level in the industrial area 8.6 ng.PAS-1d-1, 6.5 ng.PAS-1d-1, 19.9 ng.PAS-1d-1 respectively. PCB emitters are present in the industrial zone but not clearly identified. Sampling rate coefficients determined in the laboratory allow to give results in ng.m-3 and to compare with other cities. Gas particle distribution is on a range of 50:50-90:10. Thus pollutants were not considered only in the gas phase and total PCB (gas+particle) have been calculated. The ranges of variation in industrial, urban and remote area were 0.16-2.1 ng.m-3, 0.08-1.9 ng.m-3, 0.01-0.28 ng.m-3 respectively. These values were median concentration level, the highest concentrations found during particular events.

**MO 022**

**Applications of PDMS partitioning methods in the study of biodegradation of pyrene in the presence of dissolved humic acid**

MC Tejeda-Agredano[1], V Gouliarmou[2], P Mayer[2], JJ Ortega-Calvo[1]
[1]Instituto de Recursos Naturales y Agrobiología de Sevilla (IRNASE), SEVILLE, Spain
[2]National Environmental Research Institute (NERI), ROSKILDE, Denmark

Although there are reports on the inhibition of anthropogenic organic chemicals biodegradation due to binding to dissolved humic substances (HS), there is an increasing body of evidence pointing to an enhancing effect in the case of hydrophobic chemicals, like pyrene. The addition of humic fractions to contaminated soils often causes an enhanced biodegradation and desorption of these compounds from soils. Other mechanisms proposed as operating in HS-mediated enhancements of biodegradation include the promotion of compound solubility and a direct access to HS-sorbed chemicals due to the physical association of bacteria and HS. Here, we propose the use of partitioning techniques using poly(dimethylsiloxane) (PDMS) to study the effect of binding of pyrene to a dissolved humic acid isolated from soil on biodegradation of this PAH by a representative soil bacterium. The application of these techniques in biodegradation studies may solve many questions about enhancements in diffusive mass transfer, in capacity/speciation and in dissolution. Therefore, our study may provide new insights into the effects of HS on microbial degradation of polycyclic aromatic hydrocarbons (PAHs).

**In situ silicone tube microextraction: Undisturbed sampling of root-exuded artemisinin from Artemisia annua in soil**

K Knudsmark Jessing[1], N Cedergreen[1], BW Westergaard Strobel[1], P Mayer[2]
[1]University of Copenhagen, FREDERIKSBERG C, Denmark
[2]National Environmental Research Institute, Aarhus University, ROSKILDE, Denmark

The analytical determination of bioactive plant produced compounds in soil is complicated: First, the extraction from the soil can be difficult due to sorption. Secondly, it can be difficult to measure actual and representative concentrations in the soil due to a heterogenic distribution of the compounds. Thirdly, the removal of samples from the soil leads generally to disturbance of the root zone, which makes it difficult to monitor concentrations over time, e.g. a growing season. Artemisinin has well documented biological effects not just as a medicinal drug. The compound has also ecotoxicological effects, which makes it highly relevant to measure in soil. With the purpose of measuring the root exudation of the bioactive compound artemisinin from the medicinal plant *Artemisia annua*, 3 m polydimethylsiloxane (PDMS) microtube was placed in the root zone of 9 weeks old *A.annua* plants for repeated sampling without disturbance of roots and soil. The soil was covered to prevent leaching of artemisinin from the above ground biomass making root exudation the only artemisinin source. The two ends of the microtube were placed above the soil surface to allow methanol elution of the artemisinin from the PDMS microtube at various points in time while keeping the tube in place. The artemisinin content in the methanol extracts was measured using LCMS analysis. Pilot-experiments showed that 3 x 1 ml methanol were sufficient for a complete artemisinin elution. Sampling every second week over a full growing season (28 weeks) showed artemisinin contents up to 8.25 ng totally in one tube. The content in the soil peaked at week 15, whereas the artemisinin content in the above ground parts of the plant increased after week 15. Correlation between high water content in the soil and high content of artemisinin in the microtube, suggests that diffusive mass transfer in the water phase controls the kinetics of artemisinin in the system. It is surprising to find artemisinin in *A. annua* soil where root exudates is the only source, as it previously has been reported that *A. annua* does not produce or store artemisinin in the roots. In *A. annua* pots without cover, the content of artemisinin was up to 140 ng in PDMS tubes left in the soil for 28 weeks. This suggests that rain off and release from dead plant material is a major contributor of artemisinin to the soil environment.

**Use of different plastics to mimic earthworm uptake of polycyclic aromatic compounds - evaluation using chemical analysis and the H4IIE-luc bioassay**

ME Larsson, V Sjöberg, M Engwall
MTM Research Center, ÖREBRO, Sweden

The bioavailability of organic contaminants is an important factor in risk assessment of remediated soils. A method for estimating bioavailability is to measure the uptake of contaminants in earthworms. Earthworms are appropriate model organisms for bioavailability since they process large amounts of soil, have a thin permeable cuticle and play a major role in the transport of pollutants from the soil to organisms in the food chain. The use of earthworms as a model for bioavailability is quite laborious and time-consuming and the worms do not survive exposure to certain substances or concentrations. The aim of the present study was to design an easy applicable method for estimating the bioavailability of polycyclic aromatic compounds (PAHs) in soil, using plastic stripes to mimic the uptake by earthworms. Five different plastics were tested in the study, polyoxymethylene 55 μm (POM-55), polypropylene 500 μm (PP-500), polymethylpentene 76 μm (PMP-76), polyethylene therephthalate 50 μm (PET-50) and cyclic olefin copolymer 254 μm thick (COC-254). One gram of each plastic strips were mixed with approximately 40 g of a remediated PAH-contaminated soil and exposed during 14 and 28 days, in two sets, on a rotary shaker. To mimic the earthworm exposure similar conditions i.e. humidity, soil ratio, exposure time were conducted as was done in earthworm uptake studies. After exposure the plastic strips were removed from the soil and extracted with n-hexane or methanol depending on the plastic resistance. The extracts were analyzed using booth GC-MS and the H4IIE-luc bioassay. The results were compared with the PAH profile in earthworms, Eisenida fetida exposed to the same soil. Of the plastics tested, POM-55 and PP-500 agreed best with the PAH profile in the worms, both in the toxicity test using the H4IIE-luc bioassay (TEQ values) and PAH levels (ng/g).

**MO 025**

**Improved analytical performance using semi-permeable membrane extraction of lipid rich matrix**

JM Weiss, G Mariani, G Umlauf
JRC, ISPRA (VA), Italy

Lipids are good matrices to accumulate many non-polar persistent organic pollutants (POPs) due to the lipophilic nature of these chemicals. Dairy products are easily accessible and available world-wide and analysis of this matrix supplies estimation of human food chain exposure and, at the same time, reflects the contamination level of the environmental compartment from which they derive.The Stockholm Conventions and the Global Monitoring Plan encourage the production of monitoring data to effectively evaluate the presence of the POPs in all regions, in order to identify changes in levels over time, as well as to provide information on their regional and global environmental transport.

Often large sample amounts must be extracted to achieve sufficiently low detection limits of the priority POPs. Consequently, large amounts of lipids can be present in the extracts depending on the lipid content of the sample. The first step of analyzing lipid rich matrices is to extract the pollutants, preferably without extracting the lipids themselves. The presence of lipids, in the form of phospholipids, triglycerides and free fatty acids or cholesterol can disturb the chromatographic capabilities in the further clean up or fractionation steps, as well as suppresses the ionization at the chemical analysis.

Dialysis with a semi permeable membrane (SPM) enables a non-destructive separation technique of the analytes from matrix, i.e. it efficiently extracts the smaller non-polar compounds, and retaining the larger compounds in animal or plant fat samples. The membranes are made from low-density polyethylene film with approximately 1-nm pores; and enables permeation of small (analyte) molecules whereas dialysis of molecules of matrix compounds larger than this is not possible.

The aim of this study is to develop and evaluate an improved clean-up methodology for large volume lipid rich samples. 5 grams of lipids from butter has been extracted with SPM and with several different solvent compositions to identify the optimal conditions for POP analysis with sufficient recovery. The extract was further cleaned up with alumina (basic) and sulphuric acid SPE columns. The target compounds of this study are PCDD/Fs, PCBs, PBDEs, and OCPs subject to the Stockholm Convention as by 2009. Analyses are executed with high resolution GC/MS and quantifications will be carried out based on labeled surrogate standards.

**MO 026**

**Pine needles as natural passive samplers - several approaches for the extraction of polycyclic aromatic hydrocarbons**

NM Ratola[1], PA Herbert[1], S Lacorte[2], D Barceló[2], E Psillakis[3], A Alves[1]
[1]LEPAE - Faculty of Engineering - University of Porto, PORTO, Portugal
[2]Department of Environmental Chemistry, IDAEA-CSIC, BARCELONA, Spain
[3]Department of Environmental Engineering, Technical University of Crete, CHANIA, Greece

For more than two decades, numerous forms of vegetation have been studied as natural passive samplers for the incidence, bioaccumulation or travelling patterns of a wide range of persistent contaminants in the environment. Among other species, pine trees proved their effectiveness as biomonitors, essentially through the retention properties exhibited by the waxy layer of their needles. The problem is that the properties favouring the capture of such pollutants pose, at the same time, a series of barriers and limitations when it comes to the analytical steps.

In fact, the extraction and analysis of plant matrices involved in biomonitoring studies require effective extraction and clean-up procedures to retain the target compounds and eliminate the lipidic and other interfering elements. These technologies are suffering continuous development and improvement aiming for the lowest limits of detection associated with faster and more reliable methodologies.

It was our objective to compare the efficiency of several extraction (Soxhlet, ultrasonic extraction, microwave-assisted extraction, accelerated solvent extraction) and microextraction (solid-phase, hollow-fibre liquid-phase) approaches followed when needed by solid-phase extraction clean-up for the determination of the 16 EPA polycyclic aromatic hydrocarbons (PAHs) in pine needles (Pinus pinea L.). PAHs are ubiquitous carcinogenic and mutagenic contaminants resulting from natural and anthropogenic sources mainly associated to combustion processes.

All methods were compared in terms of validation parameters (detection limits, precision, recovery). Quantification was performed by gas chromatography-mass spectrometry (GC-MS), using deuterated PAHs as internal standards. Overall, the extraction approaches yielded slightly better results (with ultrasounic extraction on top) than the microextraction advances. However, the latter are also valid and not to mention much cleaner options.

**MO 027**

**An accelerated solvent extraction method for passive air sampler PUF disks**

TP Schiedek, M Laxander, S Ambs, C Schüth
TU Darmstadt, DARMSTADT, Germany

Poly-urethane foam (PUF) disks are widely used as a sorbent for e.g. passive air samplers to evaluate the air pollution with organic pollutants, such as polyaromatic hydrocarbons (PAH) or polychlorinated biphenyls (PCB). The cleaning before deployment and the extraction after the field application are usually done by standard soxhlet techniques, which last several hours or even days for each sample. Automated extraction methods for organic compounds such as accelerated solvent extraction (ASE) need usually less time for a comparable extraction efficiency and allows the repeated sequential extraction of a single sample.

The aim of this study was to develop a rapid ASE method for PUF disks. PAH and PCB standards were used as model compounds to proof the extraction efficiency. PUF disks (14 cm diameter and 1.35 cm thickness, density 0.03 $g/cm^3$, destruction temperature 180°C) were pur-

chased from Klaus Ziemer GmbH, Germany and a Dionex ASE 300 model was used to develop a method. 6 PUF disks wrapped in kimtech wipes were pre-cleaned with dichloro-methane in 100 ml extraction cells with the ASE 300 and the method parameters described below.
5 of the disks were spiked with a PAH standard (16 EPA PAH) and a PCB standard (6 Ballschmiter PCB) with an absolute mass of 500 ng for each compound. After evaporation of the solvent all disks were wetted with 20 ml natural water to simulate maximum field humidity conditions. One disk was used as a laboratory blank and treated like the spiked disks to evaluate background contamination.
Each sample was extracted with acetone under the following conditions: The cell was heated to 100°C at 100 bar for 10 min (static extraction step). Subsequently the cell was flushed with acetone (60% of cell volume) and purged for 100 s into a sampling bottle. The extraction was repeated and both extracts were combined. A third extraction was performed to reveal the extraction efficiency of the first 2 cycles.
The results showed an extraction recovery of 86 - 139 % for PAHs and 85 -105 % for PCBs (blank corrected values) with 2 cycles of the method described above. The third extraction showed concentrations lower than 5% of the target compounds. The blanks were usually lower than 1%. The total extraction time is ca. 40 minutes for each sample.

**MO 028**
**Determination of bioavailable fraction of persistent organic pollutants in freshwater sediments using two single-phase passive samplers**
R Prokeš, B Vrana, J Klánová
Masaryk University, Research Centre for Toxic Compounds in the Environment, BRNO, Czech Republic
Until recently sediment monitoring has relied on the determination of total or normalized contaminant concentrations. This approach, however, does not distinguish between freely dissolved and bound molecules and aims to assess the presence of chemicals rather than their activity and availability. Since many laboratory and field studies have demonstrated that biological effects in benthic organisms are not generally related to the total concentration of contaminants in sediments, alternative and more representative measures of the bioavailable fraction of contaminants in sediments are required. Application of passive sampling to assess bioavailability of persistent organic pollutants (POPs) in sediment can be undertaken in situ with buried passive samplers or in batch experiments in the laboratory following grab sampling or coring (and sectioning). Thanks to their simple construction, sample preparation, low cost and possible re-use, single-phase passive samplers are a suitable tool for environmental monitoring of POPs. We present results from application of single phase passive samplers based on silicone rubber (SR) and polyoxymethylene (POM) to estimate the fraction of contaminants available for desorption within a time scale of three months of as well as fraction effectively contributing to the partitioning with pore water and/or biota. Single-phase polymeric materials such as SR and POM elicit similar affinity for hydrophobic compounds and simpler sample processing, when compared with the most commonly used and commercially available semipermeable membrane devices (SPMDs). Data obtained with passive samplers can be used in risk calculations for sediment-bound contaminants with regard to any need for remedial measures for contaminated sediments and these studies would be an important input with regard to environmental quality standards for contaminants in water proposed in the EU Water Framework Directive.

**MO 029**
**Development of a new time-integrative sampler using in-situ solvent extraction for sampling polar organic compounds in water**
JH Kwon, SJ Kim
Ajou University, SUWON, South-Korea
Due to the potential fluctuation of the concentration of water contaminants, passive sampling techniques have advantages over conventional grab sampling. In spite of great success of passive sampling devices for hydrophobic contaminants such as PCBs and PAHs, integrative sampling of polar organic compounds to measure a time-weighted average concentration is still challenging because equilibrium between water and most sampling material is reached in a short time. In this study, we developed a new time-integrative sampler using in situ solvent extraction for polar organic chemicals. The sampler was composed of a 15 cm poly(dimethylsiloxane) (PDMS) tubing with the internal diameter of 0.5 mm and the wall thickness of 0.5 mm and a flow-through system of an extraction solvent (acetonitrile) through the tubing. Three polar organic contaminants, sulfamethoxazole, diuron, and 17α-ethynylestradiol, were chosen for the validation of the sampler. Without using in situ solvent extraction, the PDMS tubing could accumulate three model compounds in a time-integrative mode for less than 12 h and equilibrium between PDMS and water was obtained in a day in our laboratory conditions. However, the sampler using in situ solvent extraction could accumulate three model compounds in a time-integrative mode without limitation of exposure time. Measured sampling rates for a compound at three different extraction flow rate (0.2, 0.5, 1.5 mL $min^{-1}$) were close to each other, indicating that the overall mass transfer from aqueous solution to extraction solvent is likely to be dominated by the internal diffusion in PDMS. In addition, a pulsed exposure experiment confirmed that the new sampler worked in a time-integrative mode when the environmental concentration was highly fluctuated.

**MO 030**
**A novel methodology to determine the narcosis potential of contaminated sediments by using polyethylene samplers and comprehensive two-dimensional gas chromatography**
AP Tcaciuc[1], J Macfarlane[1], R Nelson[2], M Nipper[3], RS Carr[4], J Biedenbach[4], C Reddy[2], PM Gschwend[1]
[1]Massachusetts Institute of Technology, CAMBRIDGE, United States of America
[2]Woods Hole Oceanographic Institution, WOODS HOLE, United States of America
[3]Texas A&M University-Corpus Christi, CORPUS CHRISTI, United States of America
[4]USGS, CERC, CORPUS CHRISTI, United States of America
Narcosis has been identified as a potential toxic effect of hydrocarbon mixtures in contaminated sediments. This effect is believed to occur when the total hydrocarbon concentration in the lipid membranes of an organism reaches a critical level of approximately 0.01 g/g of lipid. We present a novel methodology to calculate the total lipid load of an organism exposed to a contaminated sediment, by using polyethylene samplers and two dimensional gas chromatography, coupled with flame ionization detector (GCxGC-FID). Previous research has shown that retention times on GCxGC can be used to predict chemical properties such as aqueous solubility and Kow. By using an appropriate training set, we extended this capability to the prediction of the partition constants between the polyethylene sampler and water (KPEW) and phospholipids and water (KPLW). With knowledge about these two partition constants, we can calculate the corresponding membrane lipid concentration for any given polyethylene sampler concentration. In addition, the amount of each compound present in the polyethylene sampler can be quantified by using the relatively constant response factor of the FID detector. The total lipid load can then be calculated by summing the contributions from individual compounds. We are applying this narcosis calculation to polyethylene sampler extracts from five sites around Boston Harbor and comparing our calculated lipid loads with toxicity data from fertilization essays and embryo development tests.

**MO 031**
**Can polar organic chemical integrative samplers be adapted for polycyclic aromatic hydrocarbons water sampling?**
N Abou Mrad, C Soulier, H Budzinski
LPTC, TALENCE, France
Polar Organic Chemical Integrative samplers (POCIS) are nowadays widely used for the monitoring of emerging hydrophilic contaminants such as pesticides and pharmaceuticals[3DOTS]. Even though their receiving phase has an affinity to aromatic groups, their accumulation capacity for polycyclic aromatic hydrocarbons is limited. In fact, laboratory calibration to assess the performance of POCIS to sample PAHs from aquatic systems showed a variability of the sampling rates over time, and that a constant accumulation rate is only achieved when the concentrations of target analytes in the POCIS membrane reach a steady state. This lag time indicates that the uptake of PAHs into the POCIS is mainly controlled by the physico-chemical properties of the polyethersulfone membrane.
POCIS extraction and analysis are relatively fast and easy comparing to the SPMD which are the conventional passive sampling tools for the monitoring of hydrophobic compounds in the aquatic system. Thus, finding an "adapted"version of POCIS to sample PAHs would be very interesting. Since we have shown that it is the POCIS membrane that does not allow the integrative kinetic accumulation of PAHs into the POCIS sorbent, the present developments consisted of changing the POCIS membrane: Nylon and polyethylene were used as replacements of polyethersulfone in an attempt to reduce mass transfer resistance, and calibrations were conducted to compare POCIS accumulation for PAHs with these three membrane types.

**MO 032**
**Comparison between classical and improved Polar Organic Chemical Integrative Sampler (POCIS) for alkylphenol polyethoxylates**
C Soulier, AW Belles, H Budzinski
LPTC, TALENCE, France
The European Union (EU) adopted the Water Framework Directive in 2000 which aims at improving and protecting the quality of the aquatic environment and its resources. The main objective is to achieve good water status by 2015. In order to control the release in aquatic systems of "priority", "priority hazardous"and emerging substances in a better way, it is necessary to develop new sampling tools which would make it possible to do without grab sampling. Indeed, despite its usefulness, grab sampling is not representative of a heterogeneous environment and of spatial and temporal variability. Passive sampling tools allow to get access to Time Weighted Average (TWA) concentrations during the deployment period. The Semi-Permeable Membrane Devices (SPMDs) and the Diffuse Gradient in Thin Film (DGT) are widely used and well calibrated. On the contrary, Polar Organic Integrative Sampler (POCIS), still require laboratory development before exposure in aquatic systems.
Alkylphenol polyethoxylates (APnEO) are ubiquitous pollutants and their concentrations are often above environmental guidelines. They were also chosen for this study due to their hydrophilic/hydrophobic properties. Calibrations of POCIS were conducted in the laboratory in tanks contaminated by APnEO with a flow through system under a controlled temperature and hydrodynamic conditions. During the first calibration, classical POCIS were studied. The uptake rate constants were determined and compared to the literature. But the results shown that APnEO were firstly accumulated in the hydrophilic PolyEther Sulfone (PES) membrane and then in the receiving phase. After 15 days, these compounds were always present in the PES membrane with a significant concentration. Thus first it appeared important to test the influence of sorbent recovery solvent on compounds elution present in PES membranes because in most studies, methanol is used as recovery solvent despite its eluant property and secondly to test other membranes which could increase the APnEO accumulation into the phase and not in the membrane In another calibration adapted POCIS-like were used with Low Density PolyEthylene (LDPE) and nylon membranes which are more suitable for the APnEO because they are more hydrophobic. These calibrations allowed the comparison of the uptake rate constants obtained with classical and adapted POCIS.
Acknowledgment: Région Aquitaine and ANR EMESTOX (ANR PRECODD 2008) are acknowledged for financial support.

**MO 033**
**Continuous Flow Integrative Sampler (CFIS). A new approach for sampling for a better control of water quality.**
JP Llorca[1], I Valor[1], RT Tortajada[2]
[1]LABAQUA, ALICANTE, Spain
[2]Labaqua, ALICANTE, Spain
Most aquatic monitoring program relies on collecting discrete grab, spot or bottle samples of water at a given time. Often, where pollutants are present at only trace levels, large volumes of water need to be collected. The subsequent laboratory analysis of the sample provides only a snapshot of the levels of pollutants at the time of ampling. However, there are drawbacks to this approach in environments where contaminant concentrations vary over time, and episodic pollution events can be missed. Passive sampling methods have shown much promise as tools for measuring aqueous concentrations of a wide range of priority pollutants.
An important limitation of passive sampling techniques resides in the fact that only the dissolved fraction (bio available fraction) is sampled. The suspended solid and colloid fraction information is not given as required in different legislations.
In this presentation, an example of the final industrial version of CFIS device will be showed to the audience and the main performance characteristics of the new developed device will be presented as well as results of the infield evaluation of the device. Limits of detection are in the range from 1 to 50 pg/L with a precision below 20%. An in field evaluation of the CFIS with priority apolar compounds including PCBs, chlorinated pesticides and PAHs was carried out for a 20 days sampling period in the outlet of a waste water treatment plant showed comparable results to those obtained with a classical sampling method.

**MO 034**
**Evaluation and calibration of a prototype passive sampler for perfluorinated alkyl acids in Sydney Harbour, Australia**

L Kaserzon[1], K Kennedy[1], J Thompson[1], AC Roach[2], JF Mueller[1]
[1]University of Queensland, COOPERS PLAINS, Australia
[2]NSW Dept of Environment, Climate Change & Water (DECCW), LIDCOMBE, Australia
Perfluorinated compounds (PFCs) have been widely used in many applications since the 1950s. In recent years their environmental and health relevance has been revealed via population studies as well as biota studies which report continual low level exposure to these compounds. Combined persistence bioaccumulation and toxicity to some animals has prompted government agencies worldwide to place regulations and restrictions on some PFC congeners. In addition the PFCs perfluorooctane sulfonate and perfluorooctane sulfonyl fluoride were added to Annex B of the Stockholm Convention on Persistent Organic Pollutants in May 2009.
To date monitoring of PFCs in aquatic systems has been predominantly facilitated by grab or composite sampling. Environmental samples are traditionally extracted using a weak anion exchange (WAX) resin to trap the alkyl acids. In this study we investigate the use of such a WAX resin in a passive sampler configuration to achieve time-weighted-average concentrations for PFCs and stipulate its use for additional acid alkyl compounds.
Data on the suitability of WAX resins as sorbent phase for PFCs, to our knowledge, were not previously published. To apply it in a passive sampler however, calibration data such as sampling rates (RS L.day-1) under environmental conditions must be available for target compounds. The aim of this study was to evaluate and calibrate a WAX polymeric phase passive sampler for PFC in a field study at Sydney Harbour, Australia. Here we present data that indicates that the WAX sorbent has the potential to make a useful adsorbent for passive sampling PFCs.

## MO 035

**On the way to bringing equilibrium SPME off-shore: development of an in-situ sampling device for persistent organic pollutants in sediment porewater**

KM Schmidt[1], G Schaffrath[1], D Ullmann[1], D Schulz-Bull[2], G Witt[1]
[1]Hamburg University of Applied Sciences, HAMBURG, Germany
[2]Leibniz Institute for Baltic Sea Research, WARNEMUENDE, Germany
Sediments are complex and variable environmental matrices which can serve both as source of and sink for persistent organic pollutants (POPs) in aquatic ecosystems. Ecologically relevant processes such as bioconcentration and baseline toxicity of POPs are mostly controlled by the chemical activity of the substance rather than by its total concentration in the sediment. Therefore, we developed a passive sampling device based on equilibrium solid phase micro-extraction (SPME) of sediment porewater.
For the purposes of validation i.e. by parallel sampling into polymer layers of different surface area to volume ratios, the device is capable of carrying sampling materials with variable formats: polymer-coated glass fibres with a diameter of up to 500 µm as well as the more flexible PDMS (polydimethylsiloxane) hollow fibres. Sampling materials are chosen as to restrict equilibration times to approximately two weeks. Encased in a copper mesh, the fibres are immersed in the surface sediment and left there for equilibration. The casing allows for long-term exposure in natural sediment systems without fibres getting broken or damaged by abrasion or the PDMS being affected by biofouling. Due to its rather small size, the device can be flexibly positioned even alongside other sampling spots like off-shore hydrographic stations. In future, the deployment in open-sea sediments is aimed for. Such measurements will help to elucidate the large-scale distribution and bioavailability of POPs in marine sediments.
Recent field studies in harbour sediments demonstrated the reliable performance of the in-situ sampling device and yielded valid results which corresponded well to those of in-vitro bioassays. In-situ equilibrium SPME proved thus a useful complementary tool in the ecotoxicological assessment of POP-contaminated sediments.

## MO 036

**Determination of silicone rubber-water partition coefficients for a wide range of compounds using the cosolvent method**

F Smedes[1], H Beeltje[2], J Balaam[3]
[1]Deltares, UTRECHT, The Netherlands
[2]TNO Built Environment and Geosciences, Environmental Analysis, UTRECHT, The Netherlands
[3]The Centre for Environment, Fisheries and Aquaculture Science, Cefas Lowestoft L, LOWESOFT, United Kingdom
To transform data from passive sampling into aqueous phase concentrations sampler water partition coefficients (Kpw) are required. These Kpws were determined for 80 compounds among which were phthalates, musk compounds, aryl phosphates, chlorobenzenes, chlorinated pesticides, some PCBs and a number of other compounds. Determinations of $K_{pw}$s were done by spiking silicone rubber sheets of 3 g with target compounds that were parallel equilibrated with water only and a range of water-methanol mixtures up to 50 %. From the measured concentrations $K_{pmix}$ values were calculated for the different methanol water mixtures. The $LogK_{pmix}$ values have an inverse linear relation with the molfraction methanol and by regression the intercept is determined being the $LogK_{pw}$ of water only. Not for all compounds equilibrium seemed to be obtained as indicated by differences in water only equilibrations where compounds were spiked to the water and where compounds were spiked to the sheets. These differences seemed not to be related to hydrophobicity but more to the character of the compounds i.e. whether a compound in addition to a hydrophobic character also contained polar groups. It is suggested that diffusion inside the sampler may reduce the rate of exchange for such compounds. Of the 80 $LogK_{pw}$s determined 80 % showed sufficient low uncertainty $sLogK_pw$<0.12) to be used for the calculation of aqueous phase concentrations in passive sampling. This 80% $LogK_{pw}$ obviously show a relation with the $LogK_{ow}$, but the error of regression (0.4) is insufficient to allow prediction of $K_{pw}$ from $K_{ow}$.

## MO 037

**What is the optimal extraction phase for your chemicals? Modeling and estimation approaches for partition coefficients between polymeric sorbents and water.**

S Endo[1], SE Hale[2], HPH Arp[2], STJ Droge[1], KU Goss[1]
[1]Helmholtz Centre for Environmental Research - UFZ, LEIPZIG, Germany
[2]Norwegian Geotechnical Institute (NGI), OSLO, Norway
The equilibrium partition coefficients between polymeric sorbent phases and water (*K*) play a key role in successful development of passive sampling techniques. A very low *K* value implies a weak affinity of the analyte for the passive sampler, and thus low sensitivity and a high detection limit. A very high *K* value implies high sensitivity, though it also leads to long equilibration times in an open system (due to the larger water volume the samplers would have to sample) and significant depletion in a closed experimental system, which prevents accurate measurement of the freely dissolved concentration. Thus, it is clear that knowing *K* values of target analytes into different polymer sorbent phases is essential for optimal selection of a passive sampling technique. However, phase selection is typically done based on time-consuming trial-and-error preliminary tests or (often not mechanistically based) 'expert guess'.
In this contribution, we present a series of experimental *K* values for different polymer phases commonly used for passive sampling, including polyacrylate (PA), polyoxymethylene (POM), polyethylene (PE), and poly(dimethylsiloxane) (PDMS). Polyparameter linear free energy relationships (PP-LFERs) are used to model and estimate *K* values. Fully predictive calculation approaches that use only the molecular structures of polymers and analytes as input parameters are also presented.
The first results show that PP-LFERs fit well to the experimental polymer-water partition coefficients and can be reliably used for estimation of *K*. The calibrated PP-LFERs suggest that PA has much higher capacities (1-4 log units higher *K*) than PDMS to extract H-bond donor compounds (e.g., phenols, amides, and many pesticides), but this is not so much the case for other types of polar compounds. Further, PA is a somewhat more efficient phase than PDMS for hydrophobic aromatic compounds.

## MO 038

**Toxicity of PAHs in the marine environment: using passive dosing to approximate the toxicity in seawater and sediments**

E Rojo-Nieto[1], C Garrido-Pérez[1], KEC Smith[2], P Mayer[2], JA Perales[1]
[1]CACYTMAR-University of Cadiz, PUERTO REAL, CADIZ, Spain
[2]Dept of Environmental Chemistry and Microbiology, NERI, University of Aarhus, DK-4000 ROSKILDE, Denmark
The acute toxicity of several PAHs at aqueous solubility to the marine crustacean Artemia franciscana nauplii was tested using both solvent spiking and passive dosing, and the results compared. The results from the toxicity tests with passive dosing were then used to establish a chemical activity-mortality relationship for PAH toxicity to Artemia franciscana nauplii. Passive dosing was then directed at reproducing the composition of a PAH mixture, measured for a coastal area of Spain (Bay of Algeciras) as part a monitoring program, in toxicity tests. HPLC analysis was used to confirm the reproducibility of the dissolved exposure concentrations for the individual PAHs and mixtures in the passive dosing tests, as well as to determine the salting-out for the synthetic seawater used. Finally, equilibrium sampling with silicone coated vials was used to measure free concentrations and chemical activities of PAHs in field sediments from this area, and the measured chemical activities in the sediment related to the chemical activity toxicity relationship obtained above for Artemia franciscana nauplii, with the aim of predicting sediment PAH toxicity. This study shows that passive dosing is a good method for toxicity testing in sea-water, maintaining constant exposure concentration over time and also being able to faithfully reproduce real mixtures of hydrophobic organic pollutants such as PAHs in sea-water toxicity tests.

## MO 039

**Microscale passive dosing ensures defined and stable gradients of hydrophobic organic chemicals**

D Gilbert[1], S Nørgaard Schmidt[2], A Winding[2], T Backhaus[3], P Mayer[2]
[1]National Environmental Research Institute, University of Aarhus, ROSKILDE, Denmark
[2]Dept of Environmental Chemistry and Microbiology, NERI, University of Aarhus, DK-4000 ROSKILDE, Denmark
[3]Dept of Plant and Environmental Sciences, University of Gothenburg, Box 461, SE-405 30 GÖTEBORG, Sweden
The environmental chemodynamics of hydrophobic organic chemicals (HOCs) are often rate limited by their diffusive mass transfer through stagnant boundary layers (SBL). This then results in concentration gradients on the microscale, which are crucial for both diffusive mass transfer phenomena and the chemotaxis of motile cells and organisms that are able to sense chemical signals. For studying both processes, practical experimental systems are needed to generate well defined and stable gradients of HOCs. At the same time the system should allow for visualisation of cell behaviour and quantitative data analysis. In the present study passive dosing on microscope slides was employed to generate diffusive gradients by partitioning between a loaded and clean polymer. Several passive dosing formats were considered among which silicone O-rings seemed to be best suited when placed in a Dunn chemotaxis chamber. Thereby an outer clean ring serves as a sink and a loaded inner ring as source, imposing a highly stable gradient on the culture medium over the distance of 1mm between the rings. This setup offers the possibility to study chemotaxis of prokaryotic and eukaryotic cells exposed to a gradient of chemical activity and to simultaneously investigate diffusive mass transfer phenomena.

## MO 040

**Integration of partition based dosing into a Skeletonema costatum microplate toxicity test**

HH Heiaas, KJ Macrae, K Thomas
Norwegian institute for water research, OSLO, Norway
The microplate toxicity test is a widely used, high throughput method to determine the toxicity of compounds and effluents to algae. One of the potential limitations of the microplate test is the underestimation of toxicity to hydrophobic compounds. This is due to the binding of hydrophobic chemicals to the test vessel, which will result in a decrease in the concentration of the substance during the test. Many of the contaminants classed as priority pollutants by the US EPA are hydrophobic. However, similar limitations have been overcome in other 96 well plate based techniques using a Poly(dimethylsiloxane) (PDMS) based carrier for the contaminants. This system allows the release of the compounds at a steady rate into the aqueous solution, a process called Partition Based Dosing (PBD). Through the use of PBD a predetermined concentration can be maintained in the test medium throughout the exposure. Such an approach, used with the microplate algal test, would allow for the toxicity testing of hydrophobic compounds much more accurately than is currently possible. Current guidelines suggest testing hydrophobic compounds by preparing Water Accommodated Fractions (WAF), by stirring and phase separation. The toxicity of three hydrophobic compounds to Skeletonema costatum were tested with both PBD and WAF procedures. Differences in measured concentration of chemicals and dose response curves between these procedures are discussed.

## MO 042

**Passive dosing of triclosan in a large-scale experiment exposing biofilm in water channels**

HG Streck[1], S Franz[1], HV Lubarsky[2], A Macherius[1], M Möder[1], M Schmitt-Jansen[1], SU Gerbersdorf[3]
[1]Helmholtz Centre for Environmental Research - UFZ, LEIPZIG, Germany
[2]Scottish Oceans Institute, University of St. An, ST. ANDREWS, United Kingdom
[3]Institute of Hydraulic Engineering, University of Stuttgart, STUTTGART, Germany
Passive dosing is an approach to establish and maintain constant freely dissolved concentrations of a compound during an experiment, e.g. in bioassays. However, up to now, passive dosing has been mainly applied in small-scale systems, such as multi-well plates but not applied to model

ecosystems in larger scales. Within a mesocosm-study looking for possible effects of the bactericide triclosan on structure and function of biofilm communities (microalgae + bacteria) passive dosing by silicon rods was successfully used to ensure stable concentrations for a period of 10 days. The experimental system consisted of glass channels filled with 3.5 litres of river water and natural biofilm grown on artificial substrate.
The passive dosing system consisted of pieces (2.52 cm) of a flexible silicon cord. Amounts of triclosan necessary to reach intended water concentrations in the water channels (2 µg/L to 150 µg/L) were estimated assuming equilibrium partitioning between the silicon rods, water and biofilm. Equilibrium partitioning coefficients were obtained from literature, and exchange kinetics were studied in a pre-experiment. In the main experiment, quick achievement of equilibrium was supported by adding stock solutions of triclosan to the water channels at the beginning of the experiment.
Water concentrations were measured throughout the experiment by micro-liquid-liquid extraction and gas chromatography-mass spectrometry in order to verify stable triclosan concentrations. Concentrations of triclosan in the biofilm and glass beads (artificial substratum < 63 µm) were analysed at the end of the experiment (day 12).
Equilibrium was reached within 2 days, and concentrations in the water phase stayed largely constant for the remaining period of the experiment. Concentrations were slightly higher (up to a factor of 2.8) than estimated by equilibrium partitioning calculations. Amounts extracted from glass beads were low (highest value: 0.21 µg g-1 dw), indicating losses to glass surfaces of the test device to be negligible. At all concentration levels, more than 84 % of the triclosan were stored within the silicon rods. High proportions of substance in the passive dosing system help to ensure a quick and efficient mass transfer to the water phase and biofilm, and are a key requirement for maintaining constant concentrations.
The experiment successfully demonstrated that the passive dosing technology can be utilized to maintain constant exposure in large-scale systems.

**MO 043**
**Passive dosing beyond toxicity testing: a new analytical tool**
V Gouliarmou[1], EC Smith[1], LW de Jonge[2], P Mayer[1]
[1]National Environmental Research Institute, Aarhus University, ROSKILDE, Denmark
[2]Faculty of Agricultural Sciences, TJELE, Denmark
The main feature of passive dosing is control of the freely dissolved concentrations by partitioning from a pre-loaded polymer. In the present study we apply this for the development of a new analytical tool to study speciation and binding of hydrophobic organic compounds (HOCs) in aqueous solutions. Further, passive dosing was applied to several medium constituents covering a wide range of interactions with HOCs. The first step of the new method is to control the freely dissolved concentration of HOCs and the second is to measure the total HOCs concentration in the equilibrated aqueous solution (=Ctotal). The measured concentration in the solution can then be combined with the corresponding equilibrium partitioning concentration in pure water (= Cwater) to determine: 1) speciation properties of aqueous samples (ff= Cwater/Ctotal) [1] 2) partitioning of HOCs with dissolved phases e.g. cyclodextrin, humic acids, micelles for determination of KDOC and KD values 3) the enhanced capacity (E) of solutions for HOCs (E= Ctotal/Cwater) and 4) salting-out effects (Setschenow constants). Application of passive dosing for speciation and binding studies has a number of advantages: 1) it is a precise and simple method, 2) it requires no phase separation step and no mass balance assumption and 3) it is possible to dose mixtures at defined and environmentally relevant free concentrations.

## EC05 - Environmental fate and exposure of Pharmaceuticals and Personal Care Products (PPCPs)

**MO 046**
**Optimization of a GC-QqQ-MS method for the analysis of siloxanes in water samples. Occurrence of siloxane in real urban wastewater samples.**
J Sanchis, M Farre, D Barceló
IDAEA-CSIC, BARCELONA, Spain
Siloxanes, and more concretely cyclic volatile methylsiloxane (cVMS) and linear methylsiloxanes (lVMS), are volatile and semivolatile organosilicon compounds which find a wide range of applications in industrial and consumer products. As an example, several of these compounds are commonly added to personal-care products (PCPs) formulations. These compounds have been used and disposed in the environment during the last decades and during the recent years have attracted considerable attention because of their persistence, bioaccumulative properties and moderate to high toxicity concern in humans. In addition, these compounds have been related to long-term toxicity [1,2] and narcotic effects [3] to several aquatic species. In addition, siloxanes have been detected in environmental samples from urban areas and also in remote areas such as the Arctic Ocean [4]. Therefore, there is a need of fast, reliable and sensitive methods for the ultratrace analysis of siloxanes in environmental samples.
The present work presents a new analytical method for the analysis of three cVMS and three lVMS based on liquid-liquid extraction followed by GC-QqQ-MS in SRM acquisition mode. The new analytical approach has presented excellent repeteabilities, offering good recoveries rates in different types of waters and achieving instrumental limits of detections ranging from 340 fg to 6.0 pg. The method was developed and validated by spiking experiments using different types of high purity water. The major contamination sources were identified and minimized in an accurate blank study, which involved the standard and sample storage, the solvent purity determination and the instrumental blanks analysis. The quality parameters of the method are presented. The method was applied to spiked and real urban wastewater samples and the results are presented.

**Optimization and validation of the chromatographic conditions for the trace analysis of pharmaceuticals used in aquaculture by means of liquid chromatography**
MA Kolodziejska, J Maszkowska, A Bialk-Bielinska, P Stepnowski, J Kumirska
University of Gdansk, Faculty of Chemistry, GDANSK, Poland
In recent years, there have been a lot of scientific reports contradicting the myth that pharmaceutical residues used in both human and veterinary medicine are not to be treated as pollutants and do not contaminate the environment. Hence, it is crucial to develop sensitive and reliable analytical methods for the trace analysis of these pollutants at low concentration level [ng/L] in the environment.
One of the major groups of contaminations are pharmaceuticals used in aquaculture. This is due to the fact that aquatic organisms are usually treated using therapeutic agents added to feed or directly to fresh water baths. There is a risk that these drugs will bioaccumulate in the water, sediment and animal tissue.
This paper presents the results of optimization and validation of the analysis of antibacterial (fluoroquinolones), anthelmintic (benzimidazoles) and antiparasite (nitroimidazoles) pharmaceuticals that are employed in aquaculture. These methods have been established using the technique of liquid chromatography. The aim of the research was to select the appropriate parameters of analysis with the highest sensitivity and accuracy. Factors that were optimized were as follows: the composition, elution program and flow rate of the mobile phase, the type of column packing, time of analysis and detection parameters. The next step was to carry out validation of these optimized chromatographic conditions. Validation parameters - such as standard deviation, variation coefficient and accuracy - were found to be within the norm for environmental samples.

**MO 048**
**Trace analysis of β-blockers and β-andenomimetics in natural water samples by SPE-GC technique with application of different types of detectors**
ME Caban, A Michalak, M Czerwicka, N Migowska, M Kwiatkowski, P Stepnowski, J Kumirska
Univesiti of Gdansk, GDANSK, Poland
One of the most relevant topics in today's environmental analytical chemistry is water quality control. In this situation, the concentrations of pharmaceuticals in aquatic system should be monitored. β-Blockers and β-adrenomimetics occur at surface water and wastewater at very low concentrations. Matrices of these samples are variable and complicated, therefore purification and concentration steps using solid-phase extraction (SPE) are necessary. The sensitivity of the used analytical methods can be improved by the application of the higher sensitive techniques of detection. Nowadays gas chromatography is one of the most selective and sensitive analytical method, but transformation of the polar analytes into volatile derivatives is required. In this work several derivatization agents (MSTFA, BSTFA, TMSI, HFBI, MTBSTFA, MBTFA, PFPA, TFAA, PFPOH, HMDS, CMDMCS) were used to prepare the appropriate to GC analysis derivatives of six β-blockers (acebutolol, atenolol, metoprolol, nadolol, propranalol, pindolol) and two β-adrenomimetics (salbutamol, terbutaline). Different kinds of detectors (e.g. MS, ECD) in GC system were tested to choose the most suitable one for trace analysis of these compounds using GC method. The results of these investigations will be discussed. Additionally, the application of the proposed procedure to analysis of natural surface water samples will be shown.

**MO 049**
**Trace analysis of pharmaceuticals in aqueous samples**
N Migowska, L Jedrzejewski, M Paszkiewicz, M Caban, P Stepnowski, J Kumirska
University of Gdansk, GDANSK, Poland
Among the anthropogenic substances that may be harmful to the environment, increasing attention is drawn by residues of pharmaceuticals and their metabolites. The environmental consequences of the presence of pharmaceutical residues depend on qualitative and quantitative composition of a 'cocktail of pharmaceuticals', which penetrated into the natural matrices and the possibility of an interaction between these substances. One of the contemporary trends of environmental chemistry is elaboration of new analytical procedures which allow to determine a wide range of analytes present at low concentrations in environmental samples during the single analysis.
In this study, the occurrence of pharmaceutical residues in water samples was examined. Investigated compounds include frequently used non-steroidal anti-inflammatory drugs (NSAIDs): ibuprofen, ketoprofen, flurbiprofen, diclofenac, diflunisal, indomethacin, aminopyrine naproxen and hormones: estrone, β-estradiol, estriol, 17α-ethynylestradiol and diethylstilbestrol. The analytical method consisted of pre-concentration and isolation of analytes using solid phase extraction, derivatisation using the mixture 99% BSTFA /1% TMCS and analysis by GC-FID and GC-MS. This procedure was applied to investigation of surface and wastewater samples collected in Poland. Up to now, only limited data about the presence of these compounds in Polish water samples are available. Therefore this study increase knowledge on this subject.

**MO 050**
**Development and validation of analytical method for determining the drug diclofenac, nimesulide and acetaminophen in surface waters from São Carlos, SP, Brazil**
HL Vicente[1], EM Vieira[2]
[1]University of Sao Paulo, SAO CARLOS, Brazil
[2]Instituto de Química de São Carlos, SÃO CARLOS, Brazil
Over the last 10 years there has been increasing interest in the study of drugs, which made the monitoring of waste gained great importance due to the fact that many of these substances are frequently found in surface waters of the cities, in concentrations ranging from $\mu gL^{-1}$ to $ngL^{-1}$. In the last few years, the occurrence of pharmacologically active compounds in the aquatic environment was recognized as one of the emerging issues in Environmental Chemistry. Recent surveys indicate that between 50 and 90% of a dose of the drug is excreted unchanged and persists in the environment, reaching water sources by passing through sewers. Diclofenac, nimesulide and acetaminophen are drugs widely consumed in Brazil and about 60% of medical prescriptions have one of the three drugs as the main agent for treatment of diseases. HPLC-DAD was used to analyze these three substances in reversed phase, using a $C_{18}$ column (250 x 4.6 mm, 5 mm), coupled with pre-column $C_{18}$ (12.5 x 4.6 mm , 5 mm), flow rate 1 mL min-1, injection volume of 20 µL, excitation at 280 nm and emission at 300 nm. A gradient mobile phase made up of methanol and water free of organics was used, both acidified with trifluoroacetic acid. Samples were pretreated with $C_{18}$ adsorbent (AgilentSampliQ OPT), 3 mL / 60 mg, conditioned with 3.0 mL of hexane, 1.5 mL of acetone and 3.0 mL of methanol. Then, 200 mL of filtered sample were percolated through the cartridge, which was dried for 10 minutes. The analytes were eluted with 10 mL of methanol. The extract was dried under gentle stream of nitrogen and reconstituted with 500 µL of methanol. After half an hour, 20 µL of sample were injected into HPLC-DAD. Table 1 presents the linear equations, the detection limits (LOD), the quantification limits (LOQ) and the correlation coefficient ($R^2$) for each studied drug.
Drug $t_R$ (min) Linear equation $R^2$ LOD* LOQ*

Diclofenac 14.74 y = 12.706x + 2.5405 0.994 0.5 1.1
Nimesulide 13.64 y = 2.1x - 1.6 0.992 0.5 1.1
Acetaminophen 9.41 y = 5.0357x - 2.0714 0.991 0.8 1.2
* $\mu gL^{-1}$
Table 1 - Values of $t_R$, LOD, LOQ and $R^2$
The proposed method was adequate for the separation and quantification of the drugs studied, and the validation parameters were considered satisfactory for acceptance of the proposed method.

### MO 051
**Optimization of chromatographic conditions to the analysis of sulfonamide residues using experimental design**
AN Macedo, RN Padovan, ALT Fornazari, EB Azevedo, EM Vieira
Instituto de Química de São Carlos, SÃO CARLOS, Brazil
Sulfonamide is an antibiotic class used in human and animal drugs. The presence of their residues in environmental and feed matrices is a great concern, because it can cause bacterial resistance, alergic reactions and intoxications, which prejudices the effectiveness of medical treatments and causes environmental and health problems. In this study, chromatographic conditions were optimized to the analysis of the sulfonamides: sulfathiazole (STZ), sulfamethazine (SMZ) e sulfadimethoxine (SDM), by using experimental design. The separation was performed on a HPLC-DAD, using a Luna C18 (100 x 4.6 mm, 5 μm) column. The injection volume was 17 μL and the wavelength was 270 nm. A complete factorial design with a central point was built to scan the significant variables, considering: flow rate, column temperature and proportion of ethanol and acetic acid in the mobile phase. The analyzed responses were the resolution ($R_S$) between the peaks and the ratio between the resolution and the analysis time ($R_S/t$). The only variable that had significant effect was the proportion of ethanol, that was negative for the separation between STZ and SMZ, and positive for SMZ and SDM. Thus, gradient elution was necessary to separate the three analytes. The gradient optimization was performed, finding out good separation using as initial condition 0:100 ethanol:water, which was ramped linearly to 20:40 at 5 min, to 40:60 at 8 min and to 50:50 at 14 min, then ramped over 1 min to 0:100. A second factorial design was built to evaluate the influence of the following variables: flow rate, temperature and proportion of acetic acid in the mobile phase. Choosing as answers the peak's height (H) and the ratio between the peak's area and width (A/w), all the variables had negative effects, that means that the best levels were: flow rate of 0.5 mL $min_{-1}$, temperature of 20 ºC and mobile phase without acetic acid. Therefore, the chromatographic conditions were optimized to the analysis of the sulfonamides using relatively low flow rate and mobile phase composed by water and ethanol, which is an renewable organic solvent less toxic than other ones traditionally used in HPLC. The linearity of the equipment to the analytes was over 0.999 for concentrations ranging from 5 to 500 μg L-1, with quantification limits under 10 μg $L^{-1}$. Thus, this is a greener chromatographic method, which can be used to analyze sulfonamide residues in environmental and feed matrices, after a suitable sample preparation.

### MO 052
**Analysis of phosphodiesterase type V inhibitors: distribution, occurrence and fate in surface water and suspended solids**
BF Silva[1], JA Acena[1], SP Pérez[1], AA Mozeto[2], DB Barceló[1]
[1]IDAEA-CSIC, BARCELONA, Spain
[2]UFSCar, SAO CARLOS, Brazil
The presence emerging contaminants like pharmaceuticals, endocrine disruptors, and illicit drugs in waters has been continuously reported in recent years [1]. The consumed amount of drugs, like stimulating drugs, is usually higher than legally prescibed quantities. Among these compounds, a class of drugs, which is often illegally acquired, includes the active ingridients of Viagra, Levitra and Cialis, namely sildenafil, vardenafil and tadalafil [2]. They have been used in therapies of erectile dysfunction acting as a selective inhibitors of phosphodiesterase type V (PDE-V) [1-3]. This work was focused on developing a method to analyze PDE-V inhibitors: sildenafil, vardenafil and tadalafil, two main metabolites (demethylsildenafil and desethylvardenafil) and also some analogues such as, hydrohomosildenafil, homosildenafil, thiosildenafil (which have been already detected as adulterants in herbal products) and norneosildenafil, which has never been detected in environmental samples. Surface water like, wastewater (influent and effluent samples) and river water were analyzed along with suspended solids to investigate the distribution of these compounds in the environment.

### MO 053
**Optimization of SPE conditions for anti-cancer drugs and antidepressants isolation**
M Paszkiewicz[1], WW Wójcik[2], LH Halinski[3], MG Golebiowski[4], JK Kumirska[3], PS Stepnowski[3]
[1]University of Gdansk, GDANSK, Poland
[2]1Department of Environmental Analysis, GDANSK, Poland
[3]Department of Environmental Analysis, GDANSK, Poland
[4]Laboratory of Environmental Chemometrics, GDANSK, Poland
Among the various compounds considered as emerging pollutants, pharmaceuticals at ng/l levels are of particular concern because of both their ubiquity in the aquatic environment and their health effects. The number of either prescribed substances, especially antibiotics and antidepressants or non-prescribed drugs,. All mentioned compounds are bioactive - they are synthesized for specific intended effects on living beings. To estimate environmental risks it is required to collect data connected with documenting contamination of the aquatic environment by these molecules. Different analytical methods are used to detect these substances in human organisms and environment. In environmental studies solid-phase extraction is extensively used to extract pharmaceutical products from aqueous matrices.
In this work analytical procedure involving solid-phase extraction (SPE) and gas chromatography-mass spectrometry (GC-MS) has been developed for determination of 7 compounds including anti-cancer drugs (flutamide, melphalan, chlorambucil) and antidepressants (doxepin, desipramine, domipramine, imipramine). Each condition affecting the efficiency of the SPE step, for example: sample pH, nature of the adsorbent in the cartridge, and the elution strength of solvents were optimized before application of the optimized procedure to environmental samples. Five different sorbents (e.g., Oasis HLB, Strata-X, Lichrolut C18, and Lichrolut EN, XAD-2 resins) have been assessed for pre-concentration as well as for clean-up of pharmaceuticals in water samples.
A sensitive, specific and highly reproducible method for the separation at the trace level has been obtained. The developed method was applied to analysis of these compounds in environmental samples.
Acknowledgement: Financial support was provided by the Polish Ministry of Research and Higher Education under grant N N204 260237.

### MO 054
**Application of solid-phase microextraction coupled with gas chromatography for the analysis of tricyclic antidepressants and anti-cancer drugs**
MG Golebiowski[1], MP Paszkiewicz[2], LH Halinski[2], NM Migowska[2], JK Kumirska[2], PS Stepnowski[2]
[1]Laboratory of Environmental Chemometrics, GDANSK, Poland
[2]Department of Environmental Analysis, GDANSK, Poland
In recent years, toxicant poisoning and environmental pollution by pharmaceuticals have received great attention. The appropriate control of these problems and prevention of related health hazards has become an important issue. Therefore, there is a need for an accurate and precise method for determining these compounds in various matrices. Currently, SPE is the most popular, well-established sample-preparation technique, with which the best sensitivity is obtained. Alternative techniques (e.g., Solid-Phase Microextraction, SPME) should be applied more often because of several advantages that they have over SPE in terms of speed, ease of sample handling and minimizing solvent use.
In this study SPME coupled with gas chromatography and gas chromatography-mass spectrometry has been used for the determination of four tricyclic antidepressants (doxepin, desipramine, domipramine, imipramine) and three anti-cancer drugs (flutamide, melphalan, chlorambucil). In SPME sampling extraction is based on the distribution equilibrium between the SPME fiber and the sample matrix. The conditions of the greatest effect on extraction efficiency such as nature of stationary phase, extraction time, temperature, rate of stirring, salt concentration (to induce a salting out effect which can enhance extraction efficiency in conventional SPME) and desorption time were optimized for all compounds. A polydimethylsiloxane-divinylbenzene (60-μm film thickness) fiber was selected after the assessment of different types of coating. The obtained SPME procedure was combined with derivatization (99% BSTFA /1% TMCS) of analytes adsorbed on SPME fiber and GC-FID or GC-MS analysis. Under optimal conditions the method was validated and good analytical performance parameters were obtained. The method has also been shown to be a useful tool for environmental application.

**Membrane assisted solvent extraction combined with large volume injection gas chromatography for the analysis of musk compounds in environmental water samples**
O Zuloaga[1], O Posada[1], M Olivares[1], A Vallejo[1], P Navarro[2], N Etxebarria[1]
[1]University of the Basque Country, BILBAO, Spain
[2]CNRS-UPPA, PAU, France
Nowadays, Personal Care Products (PCPs) are ubiquitous in the environment due to the wide use of soaps, household detergents, perfumes or fragrances. Consequently, the analysis of PCPs and their possible impact on ecosystems and biota have become in an emerging area of research. Among other compounds, synthetic musks are common compounds in fragrances and they are largely being studied due to their persistence and/or their toxicity.
In recent years, many analytical procedures have been developed for the analysis of musk fragrances in several environmental matrices such as waste-waters, sediments, sludge or biota in which both extraction and detection procedures have been optimised. The extraction and pre-concentration step take an important role since the determination of sub-ppb quantities of these compounds is usually required. Liquid-liquid extraction (LLE) or solid phase extraction (SPE) have been commonly used for these purposes. However, the current tendency is to find environmentally friendly solvent-less approaches such as solid-phase micro-extraction (SPME), stir-bar sorptive extraction (SBSE) or membrane assisted solvent extraction (MASE). Although SPME and SBSE have been already proposed for the analysis of synthetic musk in environmental matrices the later has not been taken into account as alternative extraction method.
The aim of this work is the development of an analytical approach to determine synthetic musk compounds in water samples by means of membrane assisted solvent extraction coupled to large volume injection gas chromatography. For this purpose, on the one hand, the optimisation of MASE has been carried out studying the significant variables which can affect the extraction efficiency such as extraction solvent, sample volume, pH adjustment, MeOH and NaCl addition or the type of non-porous membrane. On the other hand, factors affecting large volume injection have been also optimised in order to obtain the best sensitivity. The performance of the analytical method was validated attending to detection limits, accuracy and precision. The optimised method has been applied in real water samples to analyse these priority pollutants.

### MO 056
**Development of an analytical method for analyzing parabens and UV filters in water by LC-MS/MS**
V Boireau
Veolia Environment, SAINT MAURICE, France
The presence of pharmaceuticals and personal care products (PPCPs) in environmental samples is a topic of increasing interest.
Among PPCPs, triclosan and triclocarban are antimicrobial compounds used in soap, toothpaste, deodorants and other consumer products.
Another group of PPCPs are UV filters. These sunscreen agents are chemical compounds which are used in a variety of cosmetics (sunscreen creams and lotions).
Another group of PPCPs is made up of parabens which are the most common preservatives and bactericides in pharmaceuticals and food products. Methyl paraben and propyl paraben are the most widely used and are normally used together due to their synergistic preservative effects.
The focus of this poster is the development of a method for determining a set of personal care products from different groups in a single analysis. Parabens, UV filters and two antimicrobial agents have been determined in water samples using solid-phase-extraction followed by ultra high performance liquid chromatography-tandem mass spectrometry.
The presentation could be divided into 3 main parts:
- Development of extraction procedure and optimization of the different parameters (choice of the cartridge for solid phase extraction and choice of the solvent for elution)
- Evaluation of the analytical method in term of performance of the method (LOQ) and repro-

ductibility (recovery, relative standard deviation).
- Analysis of real samples and presentation of the first results obtained.

**Extraction and detection of Ionophores in the aquatic environment**
SA Bak, M Martin, KA Krogh, E Björklund, B Halling-Sørensen
Section of Toxicology and Environmental Chemistry, COPENHAGEN Ø, Denmark
Ionophores are the most heavily applied sup-group of the two sub-groups of anticoccidial agents, which are antiparacitic compounds used extensively worldwide as prophylactic chemotherapeutics and growth promoters in livestock production. As an example, the yearly consumptions of active compounds are more than 10 tonnes in Denmark and for the Republic of Korea more than 800 tonnes (Hansen *et al.* 2009a, Kim *et al.* 2008).
Ionophores are antibiotic drugs that form lipid soluble complexes with, primarily, alkali cations that inhibit or kill pathogenic parasites in livestock. Several reports have revealed that ionophores are emerging environmental contaminants in agricultural run-off waters, surface waters, sediments, and ground waters, due to their continuously increased and constant application as feed additives in modern livestock production (Dolliver *et al.* 2008; Hansen *et al.* 2009a and 2009b). Recent investigations has further reported that metabolites of certain veterinary drugs such as antibacterial agents (i.e. tetracyclines) and antiparacitics (i.e. ionophores) posses an environmental effects of similar level as their parent compounds on the soil bacterial community (Halling-Sørensen *et al.* 2002; Hansen *et al.* 2009c).
The focus of the present study is on the recent advances of a new analytical method for sampling, extraction and detection of ionophores in liquid matrices. The hyphenated method consists of an integrated clean-up with solid phase extraction followed by high-performance liquid chromatography tandem *in space* mass spectrometry.

**Detection of Chitosan Oligosaccharide by MALDI-TOF MS**
IK Dimzon, M Bernhard, TP Knepper
Hochschule Fresenius, IDSTEIN, Germany
Because of their increasing use in the pharmaceuticals and cosmetics industry, there is a need to study the fate of soluble, bioactive chitosan oligosaccharides and their degradation products in water. Matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF MS) offers a fast but highly selective way of detecting oligomers like chitosan.
In this study, the parameters in the MALDI-TOF MS analysis of chitosan oligosaccharide lactate were optimized to improve sensitivity of the method. 2,5-Dihydroxybenzoic acid (DHB) was used as matrix. The spots prepared by vacuum drying gave more intense and more reproducible analyte ion signals. Compared to the spots prepared by drop and dry and by quick and dirty techniques, vacuum dried spots were thinner, less crystalline, more evenly spread and with fewer hot spots.
Similar to that of other polymers, the presence of cations is necessary in the formation of ionized chitosan, mostly as sodium adducts. For better signal, however, the amount of salt was optimized by partial desaltation using Amberlite mixed-bed ion exchange resin. Fractionation by size exclusion chromatography improved the signal of the higher molecular weight chitosan.

**Comparison of online pre-concentration and direct injection volumes for the quantification of pharmaceuticals and personal care products in water with Orbitrap™ high resolution mass spectrometry**
WP Schoutsen, KJ Mchale, K Akervik, J Beck
ThermoFisher Scientific, BREDA, The Netherlands
There is a growing environmental concern regarding the health impact of trace levels of pharmaceuticals and personal care products (PPCPs) in groundwater. For this reason, the US EPA has recently developed an LC/MS/MS method for the quantification of dozens of PPCPs in environmental water sources. Prior to LC/MS/MS analyses, EPA Method 1694 calls for the solid phase extraction (SPE) of up to 1 L of water to achieve low ng/L limits of quantitation (LOQ). Instead of processing 1 L of water by the manual, time-consuming process of SPE, we present the alternative approach of on-line pre-concentration in series with LC/MS/MS using smaller volumes of water (0.5 mL) to achieve ng/L quantitation limits. For comparison, the same compounds were analyzed using a 5 uL direct injection volume without any pre-concentration. The mass spectrometer used was a High Resolution Accurate Mass (HRAM) Exactive Orbitrap instrument operated at a resolution of 50,000 and a Mass Accuracy of < 5ppm. The High Resolution in combination with the High Mass Accuracy giving the advantage to separate interfering matrix or other compound with very similar m/z values.

**Quantitative determination of endocrine disrupting chemicals and pharmaceutically active compounds in Singapore's marine environment**
C Kelly, S Bayen, S Li, C Aw, Z Zhang, F Chen
National University of Singapore, SINGAPORE, Singapore
The discharge of endocrine disrupting chemicals (EDCs) and pharmaceutically active compounds (PhAC's) into the environment via household, municipal and industrial wastes is a pressing public health issue. Many of these emerging environmental contaminants are high production volume (HPV) chemicals and thus may attain sufficiently high environmental concentrations to cause toxic effects. The objective of this study is to provide robust analytical techniques for accurate multi-residue analysis of several EDCs and PhACs in complex environmental and biological matrices such as seawater, sediments and tissues of marine organisms. Here we present development of analytical methods for the quantitative determination of several EDCs and PhAC's in surface waters, sediments and biota from Singapore's marine environment. Target analytes include a comprehensive list of brominated flame retardants (BFRs), perfluoroalkyl chemicals (PFCs), synthetic musks, plasticizers, pesticides, as well as common pharmaceuticals such as Atorvastatin, Carbamazepine, Diltiazem, Dilantin, Risperidone, Ibuprofen, Sulfamethazine, Sulfamethoxazole, Paroxetine, Cimetidine, Naproxen and Fluoxetine. We conducted a comprehensive field survey of surface waters, sediments and organisms at various locations from Singapore's coastal marine environment. Seawater samples were filtered/extracted using a filtration apparatus containing glass fibre filters and solid-phase extraction (SPE) disks in order to determine freely dissolved and particulate bound chemical concentrations. Marine sediments and tissue samples were extracted using accelerated solvent extraction (ASE) and further cleaned-up using gel permeation chromatography (GPC), SPE and/or Florisil chromatography. Identification and quantification of target compounds was performed using liquid chromatography-electrospray ionization tandem mass spectrometry (LC-ESI-MS/MS) or gas chromatography mass spectrometry (GC-MS). 13C or deuterated mass-labeled standards were used as internal standards to correct for matrix effects. Results of analyte recovery tests, procedural blanks and replicate sample analyses demonstrate generally good performance of the methods. The significance of the occurrence, levels and patterns of various EDCs and PhACs in Singapore's marine environment are discussed.

**Comparison of sorbents used in solid phase extraction to multi-residues analysis of pharmaceuticals in water samples**
N Migowska, L Jedrzejewski, M Paszkiewicz, M Caban, P Stepnowski, J Kumirska
University of Gdansk, GDANSK, Poland
Following the increasing consumption, and thus the production and excretion of pharmaceuticals, there is a high risk of penetration of these compounds to aquatic and terrestrial ecosystems. Consequently, the quality of drinking water may be endangered, so the monitoring of wastewater effluents, surface and tap water is required. The polar, water-soluble pharmaceuticals are present in trace amounts, and in the case of surface water or wastewater, they are accompanied by complex organic matter. Nowadays, modern analytical methods combine sample enrichment (solid-phase extraction, SPE), derivatization and GC analysis for trace-level detection.
The main aim of our study was to develop SPE-derivatization-GC method for the determination of 13 pharmaceuticals including non-steroidal anti-inflammatory drugs (ibuprofen, ketoprofen, flurbiprofen, diclofenac, diflunisal, indomethacin, aminopyrine and naproxen) and hormones (estrone, β-estradiol, estriol, 17α-ethynylestradiol and diethylstilbestrol). During this study special attention was taken into SPE step. Water samples were spiked with a known amount of analytes and subjected to SPE procedure with application of different types of sorbents (Oasis HLB, Strata X, Oasis MCX, Lichrolut EN, C18) and different conditions of conditioning, loading, washing and eluting steps (e.g. methanol and ethyl acetate were tested as an eluent). Recoveries and LODs values of individual target compounds were investigated. The optimized SPE procedure was combined with derivatization step and GC analysis giving the method suitability in surface and wastewater monitoring.

**Investigating the presence of pharmaceuticals and metabolites in environmental water and wastewater by UHPLC-MS/MS with triple quadrupole and time of flight mass analyzers**
F Hernández, E Gracia-Lor, M Ibáñez, R Díaz, JV Sancho
Research Institute for Pesticides and Water (University Jaume I), CASTELLÓ DE LA PLANA, Spain
Pharmaceutical residues are a matter of concern because of their wide consumption and potential negative effect on water quality and living organisms. After human and veterinary consumption, pharmaceuticals are excreted mainly as the parent compound, although many of them are also partially metabolized. Consequently, both parents and metabolites enter into urban wastewater. Most of them are not completely removed during wastewater treatments and they can finally arrive at surface and ground waters.
In this study, a UHPLC-MS/MS (QqQ) multi-class method for the determination of 47 pharmaceuticals in environmental and wastewater samples has been developed. The target list of analytes included analgesic and anti-inflammatories, cholesterol lowering statin drugs and lipid regulators, antidepressants, anti-ulcer agents, psychiatric drugs, cardiovasculars and a high number of antibiotics. Quantification and confirmation was simultaneously carried out by acquisition of two SRM transitions and the compliance of retention times and Q/q ratios.
In parallel, a wide-scope, multiclass, screening of organic contaminants based on UHPLC-QTOF MS has been developed and applied to the water samples. Around 1100 organic contaminants were investigated, including many pharmaceuticals and metabolites, but also drugs of abuse, pesticides, mycotoxins, hormones, UV-filter agents, colorants, preservants and phenols. The QTOF instrument was used under MSE mode, which allowed to obtain full spectrum acquisition data at low and high collision energies. Data at LE and HE were processed using specialized software in a targeted mode. The presence of the ion (typically the (de)protonated molecule) measured at its accurate mass (nw-XIC of 0.02 Da) at the expected retention time (if available) was evaluated. Additionally, the presence of CID fragments or a characteristic isotopic peak was assessed for the reliable identification of the compounds detected.
The developed methodology was applied for monitoring pharmaceuticals in surface and effluent wastewaters from the Spanish Mediterranean region. Using triple quadrupole target method, analgesics and anti-inflammatories, lipid regulators and quinolone antibiotics were the most detected groups. QTOF MS allowed detecting additional pharmaceuticals such as angiotensin II receptor antagonists and the diuretic furosemide, which did not form a part of the list of target analytes in the QqQ method. Drugs of abuse and pesticides were also identified.

**Determination of selected pharmaceuticals in biota from Swiss surface water using liquid chromatography-tandem mass spectrometry**
AK Zenker
University of Applied Sciences Northwestern Switzerland, IEC, MUTTENZ, Switzerland
Since numerous pharmaceuticals have been detected in the influent and effluent of waste water treatment plants or in waste water treatment plants themselves and surface water they have become an emerging issue in environmental chemistry. In most cases water samples have been collected and concentrated by solid phase extraction prior chemical analysis. However, the current project analyzed residues of polar to lipophilic pharmaceuticals from different trophic levels. The determined pharmaceuticals in fish and macrobenthon included the beta blocker Atenolol, the antihistamine Diphenhydramine, the calcium channel blocker Diltiazem, the anticonvulsant Carbamazepine, the antidepressant Fluoxetine and its metabolite Norfluoxetine, the analgetics Ibuprofen and Diclofenac. Mefenamic acid, a non-steriodal anti-inflammatory drug and Sulfamethoxazole which is a sulphonamide bacteriostatic antibiotic were also analysed.
Trace analysis of compounds was performed in liquid chromatography coupled to mass spectroscopy (LC-MS). Identification and quantification of pharmaceuticals in biota were arranged in

MS/MS mode. MRM transitions were classified in a different elution time window to increase measurement sensitivity.
Residue data from fish and macrobenthon analysis confirmed four substances (Norfluoxetine most important active metabolite of widely used antidepressant Fluoxetine, Fluoxetine itself, Diphenhydramine, Carbamazepine) to be present in biota and fish. The identified concentrations of analytes were ordinary higher in liver than in muscle tissue.

**The occurence of selected antibiotics in the southern Baltic Sea**
K Pazdro[1], GM Siedlewicz[1], A Bialk-Bielinska[2], J Kumirska[2], M Majka[2], A Fabianska[2], K Kornowska[2], P Stepnowski[2]
[1]Institute of Oceanology PAS, SOPOT, Poland
[2]Department of Environmental Analytics, Faculty of Chemistry,University of Gdansk, GDANSK, Poland
In the course of the last decade pharmaceuticals have become recognised as relevant environmental contaminants. Surface waters receive continuous inputs of pharmaceuticals, but the substances also undergo various chemical, physical and biological processes. Seas can be seen as the final sink of the most persistent compounds. However, knowledge on their behaviour and fate in marine environment, including the Baltic Sea is still very limited. Special attention should be paid to antibiotic residues. These bioactive compounds may strongly affect bacterial populations and induce biological responses in nontarget organisms due to prolonged exposures, potentially disrupting ecosystem processes. Hence, it is essential to assess the impact of antibiotics on marine ecosystems. One of the main targets in this issue is identification of their concentration levels in the environmental samples. This study report first measurements and identification of selected antibiotic classes occurring in water and sediment samples collected from the southern Baltic Sea.

**Survey of pharmaceuticals and personal care products in the Pearl River and risk characterization**
GG Ying, JL Zhao
Guangzhou Institute of Geochemistyr, GUANGZHOU, China
Ten non-steroidal anti-inflammatory drugs (NSAIDs), two blood lipid regulators (BLRs) and two anti-epileptic drugs (AEDs) were analysed in the Pearl River system (i.e., Liuxi, Zhujiang and Shijing Rivers) and four sewage effluents during the dry and wet seasons, and the environmental risks they posed were assessed. Eight pharmaceuticals were detected in the rivers and effluents, including five NSAIDs (i.e., salicylic acid, ibuprofen, diclofenac, mefenamic acid and naproxen), two BLRs (i.e., clofibric acid and gemfibrozil) and one AED (i.e., carbamazepine). The median concentrations for the eight pharmaceuticals ranged from 11.2 to 102 ng/L. Seasonal variations were not obvious for most pharmaceuticals in the three rivers except for salicylic acid and clofibric acid in the Zhujiang River, and diclofenac in the Zhujiang and Shijing Rivers. However, spatially considerable variations in the concentrations were observed for the eight pharmaceuticals in all three rivers. For most of pharmaceuticals, the effluents from the four wastewater treatment plants and Shijing River water were found to be the major discharge sources for Zhujiang River, but with additional discharge sources from some small urban streams in the wet season. Diclofenac in Shijing River was the only pharmaceutical that had a risk quotient (RQ) greater than 1, indicating a high risk to aquatic organisms in the river. The other pharmaceuticals all had RQs less than 1, indicating minimal or medium risks to aquatic organisms. Although higher RQs were calculated for the mixture of the pharmaceuticals in each river, the risk rating remained the same for the three rivers with the RQ being more than 1 only in Shijing River.

**Pharmaceuticals, sources and risk analysis**
SAE Kools, BJ Pieters, AA Vergouwen
Grontmij, AMSTERDAM, The Netherlands
The occurrence of several pharmaceutical compounds in waters has raised concern, since they are found in surface water (ng/l-ug/l) as well as in drinking water (ng/l). The current project will highlight and summarize the effort of the past couple of years. The emission from larger hospitals to smaller care institutions and nursing homes are investigated and compared with emission from households. As a final prioritization effort, the emission data are ranked based on environmental hazards. The study will highlight the emission loads of the different sources and draw conclusions for the best removal options in terms of costs and removal efficiency. The effect of the emission load of pharmaceuticals in the ecosystem depends on the dilution factor to the receiving water. Next to this, the type of pharmaceutical determines the hazard and from this, the actual risk. The study highlights that routes of the emission need to be examined to not only predict better the actual environmental concentrations and measure these, but also to indicate the best removal options.

**Occurrence and bioaccumulation of organic UV filters and UV light stabilizers in Japanese rivers and lakes**
Y Kameda[1], KK Kumiko[2], ST Shinji[3]
[1]Center for Environmental Science in Saitama, KAZO, Japan
[2]S.C. Institute of Health Science and Research, SAITAMA, Japan
[3]Tohoku university, SENDAI, Japan
We established methods of simultaneous determination of eight organic UV filters and 10 UV light stabilizers in water, sediment and biota. We applied these methods to 26 rivers and three lakes with BOD concentrations in the range of 0.6-80 mg/L. The total contaminants identified in dissolved water samples ranged from N.D. to 4,928 ng/L. Their profiles in dissolved water samples were much different among streams contaminated by domestic wastewater, sewage treatment plant effluent, rivers and lakes contaminated and little contaminated rivers. Though concentrations of UV filters and UV light stabilizers in sediment samples ranged from 1 to 6,643 mg/kg (organic carbon basis), their profiles were little different among all samples. UV-328 and UV-234 accounted for 70 to 80% of the total contaminants identified. Octocrylene, 2-ethyl hexyl-4-methoxycinnamte, benzophenone and UV-326 were also ubiquitous in sediment samples. We also measured their concentrations in aquatic biota at various trophic levels. The contaminants were detected in all biota samples at concentrations in the range of 38 -116,000 ng/g (lipid weight basis). Measuring carbon and nitrogen stable isotope ratios in biota revealed that UV326, UV-327 and UV-328 were not bioaccumulative in aquatic food webs.

**MO 068**
**Occurrence of pharmaceuticals in the settleable particulate material (SPM) of urban and non-urban freshwaters**
MS Lahti, AOJ Oikari
University of Jyväskylä, JYVÄSKYLÄ, Finland
Pharmaceuticals are a diverse group of anthropogenic chemicals continuously released to the environment, commonly detected in surface waters as concentrations ranging from ng/L to low µg/L. Besides those dissolved in discharges, wastewater treatment plants (WWTP) are also important sources of settleable particulate material (SPM), heading to sediments with suspended solids originating naturally. So far there is only little information about the occurrence and consequences of pharmaceuticals in sediment systems. The objective of this work was to study if pharmaceuticals are detected from SPM next to WWTPs or even in rural areas, thus being subtle for sedimentation.
SPM samples were collected from ten sites in Finland, grouped into reference, rural and wastewater effluent sites. SPM collectors made of stainless steel were placed to ca. 35 cm above lake or river bottom for about two months in summer. After extraction, a set of 18 pharmaceuticals was analysed with LC-MS/MS.
Several pharmaceuticals (from 8 to 13) were detected in SPM accumulated in sites next to WWTPs. Concentration of citalopram was notably high (300-1350 ng/g dw). Also bisoprolol and ciprofloxacin were detected at high concentrations (6-325 ng/g dw and 9-390 ng/g dw, respectively). On the other hand, none were detected above LOD from reference or rural sites.
There is no previous information about the presence of pharmaceuticals in SPM. Our results show that pharmaceuticals are sorbed to particles in WWTP and nearby, eventually ending up into sediments. These results also indicate that pharmaceuticals are not markedly contaminating the sediment in rural areas. In urban habitats however, depending on persistence and bioavailability, sediment-bound pharmaceuticals may affect benthic invertebrates and habitats. However, more data are needed for the fate and ecotoxicity assessment of risks to the benthic biota.

**MO 069**
**The presence and fate of pharmaceuticals and personal care products (PPCPs) in wastewater and Charleston Harbor, South Carolina, USA**
ML Hedgespeth[1], YV Sapozhnikova[2], EF Wirth[2]
[1]Lund University, LUND, Sweden
[2]NOAA/NOS/National Centers for Coastal Ocean Science, CHARLESTON, SC, United States of America
Pharmaceuticals and personal care products (PPCPs) are considered to be a group of emerging contaminants that includes over-the-counter, prescription, and veterinary drugs, as well as chemicals found in cosmetics and common household products. These chemicals may be introduced into aquatic environments by non-point and point sources including domestic wastewater treatment plant effluents. This study assessed seasonal and regional trends of PPCPs detected in samples from two local wastewater treatment plants (WWTPs) and surface water from the Charleston Harbor over the period of twelve months. After modifying EPA Method 1694 to include hormones, analysis using HPLC/MS/MS revealed that of the 19 target compounds examined, 11 were quantified above method reporting limits in wastewater influent, 9 in effluent, and 7 in surface water samples. Concentrations were reduced by > 90% for most chemicals in effluent compared to influent, though concentrations of some PPCPs in effluent were higher than those in influent. Differences in effluent concentrations and estimated removal between WWTPs are believed to be related to variation in general operating parameters and/or the anoxic basin employed by one of the facilities. Overall, future monitoring of PPCPs may aid in minimizing potential negative impacts of increasing urban/industrial development in coastal regions.

**Broad screening of organic chemicals in Dutch groundwater and their occurrence in relation to land use and hydrology**
L ter Laak[1], LM Puijker[1], JA van Leerdam[1], J Raat[1], P de Voogt[2], AP van Wezel[1]
[1]KWR Watercycle Research Institute, NIEUWEGEIN, The Netherlands
[2]IBED-University of Amsterdam, AMSTERDAM, The Netherlands
Groundwater is considered a valuable non-renewable resource for drinking water. It is therefore important to monitor groundwater quality, assess the vulnerability of groundwater wells, and identify anthropogenic activities that can result in groundwater contamination. In this study high resolution mass spectrometry (hybrid linear ion trap (LTQ) FT Orbitrap MS) was applied to screen for a broad range of more than 600 known and unidentified (polar) organic chemicals. Nearly 400 chemicals were observed, of which 82 could be identified and more than 313 could not be identified.
The results obtained were interpreted in relation to the source characteristics and land use. Groundwater that was affected by landfills showed the highest total MS response (ion counts) and most individual chemicals and was therefore considered most contaminated, while river bank filtrated water was generally more contaminated than phreatic groundwater, and groundwater from (semi-)confined aquifers was most pristine. Additionally, industrial chemicals were more frequently observed in river bank filtrated water and pesticides were more frequently observed in water originating from rural areas. Finally, the applied broad screening technique illustrated that only 42 ± 25% of the ion counts came from known chemicals. Screening for both known and unidentified chemicals provides more information on the over-all water quality and reveals that there is a 'blind spot' considering the total pool of organic contaminants in the environment.

**MO 071**
**Using GIS to establish an emission type based sampling scheme with passive samplers in Luxembourg**
T Gallé, V Huck, C Braun, J Wilkinson, M Bayerle
CRP Henri Tudor, ESCH-SUR-ALZETTE, Luxembourg
Waste Water Treatment Plants (WWTP) have been identified as a major source for pharmaceuticals in river networks in recent years. WWTPs remain neglected as a source for pesticides although a substantial body of evidence shows that especially for chronic exposure WWTPs have a significant impact. Monitoring xenobiotics is a cumbersome and costly endeavour if the dynamics of the emissions are to be taken into account. The other aspect is the identification of locations where the exposure is expected to be the highest and most frequent. This poster presents an approach which used GIS and WWTP information to identify typical immission situations in Luxembourgish rivers. The following five immission situations were considered: Rivers impacted by high WWTP discharge, subdivided in those with more urban connections to the WWTPs and those with farms owning lots of agricultural land. The latter are more prone to emissions from left-over spilling of pesticides and spraying equipment cleaning. The second source group targets runoff from surfaces with low- and high infiltration soils and impermeable urban surfaces as categories. All Luxembourgish water bodies have been analyzed with a GIS system in order to isolate monitoring locations that would best correspond to one of the categories defined above.

Twelve sampling locations have been monitored in the main pesticide application seasons with 14 day passive sampler exposure summing up to 4 months monitoring at each spot. The results served to establish a ranking of most detected pesticides and pharmaceuticals and to verify the soundness of the allocated emission sources. In addition the mean exposure has been compared to ecotoxicological assessment methods such as SPEAR, toxic unit as well as pesticide mixture evaluation. The poster discusses the combination of GIS and passive samplers as a reliable monitoring approach.

**Determination and distribution of triclosan and methyl triclosan in estuarine settings**

MG Pintado-Herrera, E Gonzalez-Mazo, PA Lara-Martín
Universidad de Cádiz (Spain), CÁDIZ, Spain

Triclosan (TCS), an antibacterial agent, and methyl triclosan (Me-TCS), TCS degradation product, are sewage-derived contaminants. A method for the determination of both compounds in sediment and water samples has been optimized. For solid samples, extraction and cleanup were integrated into the same step using pressurized liquid extraction with in-cell-clean-up. Sediments (4 g) were homogenized with sodium sulfate anhydrous and introduced in a 11 ml stainless-steel extraction cells containing 1g of Florisil. The extraction was performed using dichloromethane at 100 ºC, 1500 psi and 3 static extraction cycles of 5 min each. For water samples, stir bar sorptive extraction-liquid desorption (SBSE-LD) has been used. Stir bars coated with polydimethylsiloxane (PDMS) were placed in a flask containing the water samples (100 ml) and stirred for 24 hours at room temperature. Then, the bars are sonicated during 30 min using acetonitrile to release the analytes. Me-TCS and a silylated derivative of TCS were determined by gas chromatography -mass spectrometry (GC-MS). Recovery experiments in water and sediments were performed and the results ranged from 65-144%. Limits of quantitation (LOQs) were 15 ppt for TCS and 10 ppt for Me-TCS, in water samples, and 0.1 ppb for TCS and 0.2 ppb for Me-TCS, in solid samples. The method was validated by carrying out a sampling in the estuary of Guadalete River (SW Spain). TCS and Me-TCS concentrations up to 9.6 ppb in sediments and 310 ppt in water were measured. Their distribution in sediments was affected by the presence of wastewater discharges, where maximum concentrations were detected. Highest values were reached in the water column during low tides as the water volume in the estuary becomes lower.

**One year monitoring of pharmaceuticals in aquatic systems: acquisition of data concerning fate and behaviour in surface and groundwaters**

A Togola, S Bristeau, L Amalric
BRGM, ORLEANS, France

Occurrence of pharmaceutical products in aquatic systems has been highlighted for few years, showing a potential sanitary and environmental impact on water quality. The present work deals with monitoring of 70 stations located in Loire -Brittany river basin, including surface waters and groundwaters. 40 pharmaceuticals and veterinary products including metabolites and owning to the main therapeutic groups were monitored in Summer 2009 and Winter 2009-2010 in order to document seasonal variability and assess contamination level in French aquatic systems. Two rivers were particularly monitored, with monthly sampling of 4 stations spreaded over the river from upstream to downstream of WWTP discharge, to better understand seasonal variations, fate of pharmaceuticals and impact of WWTP effluent introduction in the river.

Results gave a global overview of the pharmaceutical contamination. Frequencies of detection depending on the type of water and the land uses in impacted river basin allow to determine "key pollutants"that can be used as tracers of pharmaceutical pollution, considering on the other hand their persistency or their high reactivity in aquatic systems.

**A multi-component snapshot of new pharmaceuticals and pesticides in the river Meuse**

CJ Houtman[1], K de Jong[1], J de Jong[1], AC de la Mar[2], K Lekkerkerker-Teunissen[3], J Kroesbergen[1]
[1]The Water Laboratory, HAARLEM, The Netherlands
[2]Aqualab Zuid, WERKENDAM, The Netherlands
[3]Delft University of Technology, DELFT, The Netherlands

The river Meuse serves as drinking water source for over six million people in France, Belgium and the Netherlands. In 2009, over 500 million m3 surface water from the Meuse was abstracted for this purpose. Rapid improvements in chemical and bio analytical techniques have led to the discovery in surface waters of all kinds of so-called emerging contaminants at (sub) ng/L to µg/L concentrations, including pharmaceuticals, illicit drugs, sweeteners, perfluorinated compounds, and various steroid hormones. Drinking water companies therefore intensively investigate their water sources for the presence of emerging contaminants and their fate during purification processes. Pharmaceuticals and pesticides, both developed to be biologically active, are important classes of contaminants present in the river Meuse.

In this study, sensitive and specific multi-component methods on UPLC-MS/MS were developed for the analysis of new pharmaceuticals and pesticides. The methods were applied to analyse water samples from 15 locations along the Dutch catchment of the Meuse. In this way, a snapshot was made of its chemical water quality with respect to pharmaceuticals and pesticides. The results were used to estimate the contribution of specific emission sources (industry, WWTP, agriculture) in the catchment. Multiplication of measured concentrations with water discharge data was performed to assess the (bruto) loads of pharmaceuticals and pesticides transported to the North Sea and the contribution of activities in the Dutch catchment to these loads.

**First reports of pharmaceuticals and personal care products from Ushuaia, Tierra del Fuego, Argentina**

WD di Marzio[1], S Diodato[2], L Comoglio[2], ME Sáenz[3]
[1]CONICET-PRIET-DCB-UNLU, LUJÁN, Argentina
[2]CADIC - CONICET, USHUAIA, Argentina
[3]CONICET-PRIET DCB UNLU, LUJÁN, Argentina

Ushuaia is commonly regarded as the southernmost city in the world, is located in a wide bay on the southern coast of Isla Grande de Tierra del Fuego, bounded on the north by the Martial mountain range and on the south by the Beagle Channel. Ushuaia has developed on the coastal areas adjacent to Ushuaia and Golondrina Bays and currently has approximately 64.000 inhabitants. For 20 years, the entire coastal area has been receiving input from sewage, industrial and port, producing visible changes, some of them partially quantified. In particular is concerned generally poor and inadequate functioning of the sewage collection system and dispersant, located at the western end of the Ushuaia Peninsula, which has led to the discharge of untreated sewage along the coast. We study the drainage channels that cross the city, which receive the discharge of all types of wastewater. The samples were characterized by measuring physical and chemical parameters: dissolved oxygen, conductivity, salinity, turbidity, pH, temperature, total hydrocarbons, BOD, COD, soluble phosphorus, ammonia, nitrates, fat and oils, fecal and total coliforms, algal, cladocerans and fish acute toxicity, and chronic toxicity to Daphnia magna. Analytical determination of Pharmaceuticals and Personal Care Products compounds in surface water were performed by manual solid-phase microextraction with unbonded fibers of polydimethylsiloxane at a stationary phase of 100 and 7 µm thickness and one of 85 µm of polyacrylate that were injected into a GC-MS. The main substances determined were: Personal Care: Benzyl cyanide, Benzyl oleate, Tetramethyl octacosanol, Decylhydroxylamine, Acids: Myristic, Hexanoic, Decanoic decyl ester, Cyclopentaneundecanoic, Hexadecanoic methyl ester, Didecil ether, Naphthalenone, benzophenone, Ethanol Tetradecyloxy, Musklactone, Isopropyl Myristate, Octadecane, Ethanol dodecyloxy, Benzeneacetonitrile, Biphenyl Diethyl. Pharmaceutical: Di-Tert-Butyl Benzoquinone, Oleamide, Nandrolone, Acenaphthene, Urea, Oxabicyclo-Octane, Tetradecanoic Acid Methyl, Serinol, Oxonanone, Cyclohexanone, Dodecane chloro, Phenol dimethylethyl, Dodecanamine dimethyl, Indolizine. Others: Trichlorophenol, Diphenyl, Octamethylcyclotetrasiloxane, Tributyl phosphate, Eicosanol, Ethanediol monoformate, Naphthalene Ethenyl, Aminoheptadecane. Many of the detected compounds are included as those with High Production Volume since their environmental impact could be relevant and should be assessed.

**Occurrence and fate of selected pharmaceuticals in biotic and abiotic compartments from water bodies directly impacted by reclaimed water irrigation.**

J Wang, PR Gardinali
Florida International University, NORTH MIAMI, FLORIDA, United States of America

Municipal wastewater has been recognized as one of the main routes bringing pharmaceuticals and personal care products (PPCPs) into the environment. Fish, however, are a sensitive indicator of what substances may be entering our water systems. In this study, we have developed methods for the analysis of 11 pharmaceuticals representing multiple therapeutic classes in fish tissues, sediments and pond water directly affected by reclaimed water. 1 g of fish tissue and 2 g of sediment were extracted by methylene chloride using accelerated solvent extraction followed by mixed-mode cation exchange cleanup and analyzed by liquid chromatography-tandem mass spectrometry (LC-MS/MS). Compared to the previously reported methods, developed protocol offers cleaner extracts giving lower method detection limits (MDLs) for 10 out of 11 selected pharmaceuticals. A simple SPE method was used to concentrate and cleanup all 11 pharmaceuticals in reclaimed water and thesurface waters from where fish were collected. During the period of a month, 9 out of 11 selected pharmaceuticals were continuously detected in reclaimed water, but only caffeine, diphenhydramine and carbamazepine were detected in fish tissue and pond water samples. Analysis of the pond sediments and some bottom feeders confirmed that pharmaceuticals such as fluoxetine and diltiazem were quickly removed from surface waters due to the adsorption to sediments where they seem to be persistent. To teh best of our knowlegde this is the first report of the potential accumulation of caffeine in fish tissue.

**MO 077**

**National substance flow analyses for the assessment of illicit drug abuse using a sewer epidemiology approach**

U Khan, J Nicelll
McGill University, MONTREAL, Canada

Sewer epidemiology is an emerging field that relies on the measured concentrations of select active pharmaceutical ingredients (APIs) in wastewater influents to estimate the prevalence of illicit drug abuse within the wastewater contributing community. However, for certain illicit drugs of abuse the most suitable marker compound may not only originate from illicit abuse of the drug but also from multiple licit sources. In particular, the suggested API markers for heroin, amphetamine, and methamphetamine abuse are, respectively, morphine, unchanged amphetamine and unchanged methamphetamine, all of which have multiple licit sources that could lead to these APIs being released to sewers and hence be present in wastewater influents. Hence, recognizing that from a sewer epidemiology perspective the main interest lies in quantifying the fraction of such APIs that originates exclusively due to illicit drug use, it is important to compare the relative contributions of such a source to those that are expected to be realized through all licit sources. Further, by conducting such an analysis on a national level for many different countries, one can assess whether the sewer epidemiology approach for tracking the abuse of heroin, amphetamine and methamphetamine is more feasible in certain countries than others. The primary goal of this communication is to precisely address such concerns. Results obtained suggest that in certain countries sewer epidemiology can be readily used to monitor the abuse of such drugs, whereas in other countries consumption patterns of licit sources for relevant APIs are such that sewer epidemiologist are cautioned on exclusively relying on such a methodology. For example, when considering a substance flow analysis for morphine, which is the marker for heroin use, the results obtained suggests that in most European countries (with the exception of Scandinavian countries), a dominant or significant fraction of the sewer morphine load is expected to originate due to the populations' abuse of heroin. In contrast, in North American countries, the majority is expected to primarily originate due to the consumption of medicinal drugs that are metabolized to morphine.

**MO 078**

**Persistency assessment and aerobic biodegradation of selected cyclic sesquiterpenes present in essential oils**

J Jenner[1], G Kreutzer[2], P Racine[3]
[1]Givaudan UK Ltd, ASHFORD, United Kingdom
[2]Givaudan Suisse SA, VERNIER, Switzerland
[3]Robertet SA, GRASSE, France

Sesquiterpenes are ubiquitous in essential oils but an assessment of their environmental behaviour is still required for their use as components of natural fragrance ingredients and oral care flavours. Persistency plays a key role in hazard and risk assessment, but the current knowledge on the biodegradation of sesquiterpenes in the aquatic environment is limited. This could have important consequences for PBT/vPvB assessments of essential oils since most of the sesquiterpene components, especially hydrocarbons, have a logKow of > 4.5 and are identified as potentially bioaccumulating according to REACH screening criteria. This work describes the results of a persistency screening assessment for a number of representative sesquiterpenes present in essential oils. Some of these natural sesquiterpenes contain structural fragments, such as quaternary carbon atoms and fused or bridged ring systems, which are often associated with poor biodegradability in xenobiotic organic chemicals. Current biodegradation prediction models (BIOWIN, BioHCwin and CATALOGIC) were found to be of limited use since most of the sesquiterpenes studied were outside the structural domain of the models. Aerobic biodegradation was measured in a standard or prolonged OECD 301F ready biodegradability test. Ten out of eleven sesquiterpenes tested achieved significant ultimate biodegradation (ranging from 51% to 88% BOD). Germacrene D achieved 24% ultimate biodegradation and specific analysis at the end of the test indicated complete primary degradation. Given that the shape of the biodegradation curves indicates poor bioavailability and ready biodegradability tests are very stringent, it is expected that all the sesquiterpenes tested in this study would be degraded under environmental conditions. This evidence of non-persistence may be used to read-across to other natural sesquiterpenes within the same carbon skeleton family which are expected to follow similar biodegradation pathways.

**MO 079**

**A tiered procedure for assessing the formation of biotransformation products of pharmaceuticals and biocides during activated sludge treatment**

K Fenner[1], S Kern[2], R Baumgartner[3], DE Helbling[1], H Singer[1], MJ Loos[1], RP Schwarzenbach[3], J Hollender[1]
[1]Eawag, DÜBENDORF, Switzerland
[2]Givaudan, DÜBENDORF, Switzerland
[3]ETH Zurich, ZÜRICH, Switzerland

Upon partial degradation of polar organic micropollutants during activated sludge treatment, transformation products (TPs) may be formed that enter the aquatic environment in the treated effluent. However, TPs are rarely considered in environmental risk assessments of wastewater-relevant compound classes such as pharmaceuticals and biocides. Here, we suggest and evaluate against field data a tiered procedure, including a fast and inexpensive initial screening step based on HR-MS/MS and a subsequent confirmatory quantitative analysis, that should facilitate consideration of TPs formed during activated sludge treatment in the exposure assessment of micropollutants. At the first tier, potential biotransformation product structures of seven pharmaceuticals (atenolol, bezafibrate, ketoprofen, metoprolol, ranitidine, valsartan, and venlafaxine) and one biocide (carbendazim) were assembled using computer-based biotransformation pathway prediction and known human metabolites, and screened for in sludge-seeded batch reactors using high-resolution tandem mass spectrometry (HR-MS/MS). The 12 TPs found to form in the batch experiments were then searched for in the effluents of two full-scale, municipal wastewater treatment plants (WWTPs) to confirm the environmental representativeness of this first tier. At the second tier, experiments with the same sludge-seeded batch reactors were carried out to acquire kinetic data for major TPs that were then used as input parameters into a cascaded steady-state completely-stirred tank reactor (CSTR) model for predicting TP effluent concentrations. Predicted effluent concentrations of four parent compounds and their three major TPs were corroborated by comparison to 3-day average influent and secondary effluent mass flows from one municipal WWTP. CSTR model-predicted secondary effluent mass flows agreed within a factor of two with measured mass flows and confidence intervals of predicted and measured mass flows overlapped in all cases. The observed agreement suggests that the combination of batch-determined transformation kinetics with a simple WWTP model may be suitable for estimating aquatic exposure to TPs formed during activated sludge treatment. Overall, we recommend the tiered procedure as a realistic and cost-effective possibility to include consideration of TPs of wastewater-relevant compounds into exposure assessment in the context of chemical risk assessment.

**MO 080**

**Pharmaceutical P450 metabolism: read-across from human ADME to environmental Transformation Products (TPs)**

F Ericson
Pfizer Inc, GROTON, CT, United States of America

The potential risk of transformation products from wastewater treatment and subsequent water-sediment release environment is a current topic of interest given the advances in analytical chemistry and increase detection of pharmaceuticals and their metabolites in the environment. TPs are presumed to be less toxic than parent based on known P450 mechanisms of transformation and its role is detoxification. They are generally not considered in the risk assessment unless there is a need to mitigate a high risk quotient based on the parent compound. The current trigger for TP identification is linked to the outcome of the OECD 308 based on its presence > 10% dose observed during the study.
This poster presents the learnings from identification of TPs from water-sediment studies and compares findings to what is seen in published human absorption, disposition, metabolism and excretion (ADME) studies. Case studies are provided to highlight the potential use of reading- across from human ADME studies to environmental transformation products as a means of assessing their relative risk to parent compound. It is the intent that such data will support constructing a knowledge base around environmental microbial transformations and further discussions around how best to approach environmental transformation products in the environmental risk assessment and further clarify when identification and follow on testing is needed.

**MO 081**

**Sediment-water test systems to evaluate the environmental fate of pharmaceuticals - how representative are the results?**

M Radke[1], M Maier[2]
[1]Stockholm University, STOCKHOLM, Sweden
[2]HelmholtzZentrum, Institute of Groundwater Ecology, MÜNCHEN, Germany

Sediment-water tests are an established tool to assess the persistence of pharmaceuticals and other organic micropollutants in aquatic systems. To assess the environmental fate of a number of pharmaceuticals, especially some acidic compounds (e.g., ibuprofen, naproxen) and beta-blockers (metoprolol, propranolol), we carried out a series of such tests with river sediment and synthetic river water. We compared sediment from two different rivers (Roter Main, Germany; Säva Brook, Sweden), sediment from several locations within one river, and sediment sampled at two different points in time. Tests were carried out at a concentration of 100-200 µg L-1 over approx. 30 days; samples were filtered and subsequently analyzed by UPLC-qTOF-MS.
All test compounds dissipated from the test systems, with dissipation half-lives between 2.5 and 50 days. Dissipation half-lives in tests with sediment sampled from the same location at two different times were generally varying up to approximately 45 %. Tests with sediment from different locations within one river provided similar dissipation times for ibuprofen and furosemide, while substantial differences were observed for naproxen and the two beta-blockers. When comparing the two rivers, dissipation half-lives for naproxen were in the same range, while substantial differences were observed for furosemide and ibuprofen. Especially the results for ibuprofen are remarkable - this compound is generally know as rapidly biodegradable, and the half-lives with sediment from Roter Main were generally shorter than 5 days. In contrast, the tests with sediment from Säva brook resulted in a half-live of 45 days.
In general, the results of this study allow the assessment of inherent uncertainties and limitations of such laboratory tests. Not only are the results depending on the specific set-up of the tests, but also on the nature of the specific sediment, the sampling location and other variables. We did not observe any systematic patterns in the test results, they seem to be depending on the specific combination of sediment and test substance. Variations of dissipation half-lives of up to one order of magnitude were observed, highlighting the need for a critical evaluation of such test results and also the need for further improvements in the design of such tests.

**MO 082**

**Partitioning of sulfadiazine to soil colloids in the water and soil/biosolid interface**

GG Anskjær, KA Krogh, B Halling-Sørensen
University of Copenhagen, COPENHAGEN, Denmark

In animal husbandry, a broad range of veterinary pharmaceuticals is used for therapeutic purposes or as growth promoters. A frequently antimicrobial used in e.g. pig production is sulfadiazine which belongs to the large group of sulphonamides antimicrobials that is used to treat bacterial infections and as growth promotors. In recent years the fate of sulfadiazine in the environment has been widely studied. Several papers have indicated a build up of non-extractable residues in soil. Formation of non-extractable residues has been identified as a major route of dissipation in soil. However, a general understanding of the mechanisms regulating the behaviour is still to be understood. Especially, partitioning and transport at the soil/water interface in the soil environment are important factors to describe. To elaborate, a sorption test system was applied based on Escher and Schwarzenbach (1996). Sorption at the soil colloid/water interface and the dependence of pH and ionic strength were main focus areas.
With the proposed test system we are able to describe a partitioning scenario in a well-defined theoretical manner. Effects of pH (2 - 12) and ion strength (cation concentrations in the range of 0.001-1 mol/L) on the distribution of sulfadiazine in the soil colloid/water interface were studied to give an in-depth understanding of the dissipation in the soil environment.
Furthermore, the results of biosolid amendment to soil are investigated to get an understanding of the changes in the interface environment when adding organic material, hereby mimicking soil management on micro scale.

**MO 083**

**On a way to understand the fate and behaviour of sulfonamides in the environment**

AM Bialk-Bielinska[1], A Chojnacka[1], M Korzekwa[1], M Borecka[1], W Mrozik[2], J Kumirska[1], R Palavinskas[3], P Stepnowski[1]
[1]University of Gdansk, GDANSK, Poland
[2]Medical University of Gdansk, Department of Inorganic Chemistry, GDANSK, Poland
[3]Federal Institute for Risk Assessment BfR, BERLIN, Germany

Thanks to their low cost and their broad spectrum of activity in preventing or treating bacterial infections, sulfonamides (SAs) are one of the oldest groups of veterinary chemotherapeutic agents, having been used extensively for more than fifty years. As these compounds are not completely metabolized in animals, a high proportion of them are excreted unchanged in feces and urine. Therefore, they are released either directly to the environment in aquacultures and by grazing animals or indirectly during the application of manure or slurry. Once released to the environment, SAs distribute themselves among different environmental compartments, along with their degradation products, and can be transported to surface water and groundwater. The physicochemical properties, the dosage applied and the nature of the environmental components with which they interact, govern the whole process. In surface waters, these substances may partition to sediments and/or undergo abiotic (photodegradation and/or hydrolysis) and biotic degradation. SAs are recognized as quite persistent, non-biodegradable compounds, which explains the fact that in the last ten years they have been regularly detected in aquatic and terrestrial environments. However, the knowledge on the behavior and fate of these rather polar pollutants in the environment is still limited, especially from a process-oriented point of view. Understanding the effects of individual processes is crucial for analyzing potential risks caused by the presence of pharmaceuticals in the environment.
Therefore, in the present study, the assessment of abiotic hydrolytic transformations in aquatic systems at pH values normally found in the environment (pH 4 - 9) and sorption of sulfonamides onto sediments was determined. Described experiments were performed according to the existing OECD guidelines. HPLC-UV method was used for the hydrolysis and sorption experiments and LC-MS/MS technique for the determination of potential degradation products. The mechanism of sulfonamides sorption onto selected natural soils differing in their organic content, cation exchange capacity and particle size distribution was investigated in detail. Isotherms were employed to describe sorption. The influence of external factors on sorption, such as ionic strength and pH, were also determined.
Obtained results play a crucial role not only in description of the mobility and transport of those compounds but also their stability in the environment.

**MO 084**

**Sorption of sulfaguanidine to soils differentiated in their physicochemical properties**

J Maszkowska[1], M Kolodziejska[1], A Bialk-Bielinska[1], W Mrozik[2], P Stepnowski[1], J Kumirska[1]
[1]University of Gdansk, GDANSK, Poland
[2]Medical University of Gdansk, GDANSK, Poland

Sulfonamides are one of the most commonly used drugs in veterinary pharmacotherapy. Their relatively low cost and broad spectrum of antimicrobial activity made them usual choice in animal breeding (i.e. food additives). However the use on the large scale results in real danger for various environmental components. Studies reported that even 30% of antibiotics used in recent years in the European Union in animal husbandry were applied as non-therapeutic agents (e.g. as growth promoters).
Sulfaguanidine is one of the widely used sulfonamides and it is typically utilized as food additive in pastures. By the grazing animals or manure application, this compound can spread into the natural environment by uncontrolled way. Natural components such as soil and sediments are in the major risk, therefore it is important to determine the mobility and the possible interactions of sulfoguanidine in these matrices. Such studies allow to appraise the possibility of infiltration of sulfoguanidine into the groundwater or run off with surface water, and eventually assess the risk to human health and the natural environment.
The aim of this study was to determine the sorption of sulfaguanidine in soils differentiated in their physicochemical properties such as: pH, organic matter content and cation exchange capacity. The strength and the extent of the sorption phenomena were determined by sorption coefficient, isotherms and sorption kinetics. To assess the sorption type, the results were tested by Langmuir and Freundlich model. The influence of external factors, on sorption of sulfaguanidine, like solution pH and ionic strength were also determined. The degree of sorption of this compound to soils was quantitatively assessed using HPLC technique with UV/Vis detection.

**MO 085**

**Influence of non-hydrophobic factors on the sorption of ionizable xenobiotics to solids**

HC Holten Lützhøft, A Franco, S Trapp
Technical University of Denmark, KGS. LYNGBY, Denmark

It is well known that xenobiotics sorp to solid phases like soil and sediment, depending on their inherent properties and environmental conditions. Traditionally it was accepted, that the hydrophobicity of the chemical, i.e. the log $K_{OW}$, as well as the solid's content of organic carbon (OC) were the parameters describing the extent of sorption. Realizing that ionizable chemicals like weak acids and bases not always sorb according to their hydrophobicity, a correcting factor has been suggested. Correcting the hydrophobic sorption according to the Henderson-Hasselbalch equation has recently shown to improve the predicted sorption of weak acids significantly, however, weak bases do still show discrepancies compared with experimental data. In this investigation it was studied how a range of electrostatic parameters have influence on the sorption of weak bases to solid phases. Besides log $K_{OW}$, pH and OC content of the solids, this investigation also included parameters like clay, silt and sand content, cation exchange capacity, zeta potential and other properties of the solids, and the impact on the sorption of weak bases to solids. Weak bases with $pK_a$-values differing about half a unit in the range 4-9, resulting in ionization within an environmental relevant pH range, are selected for the study. Literature is searched for data on distribution coefficients (log $K_D$) where also information about the experimental conditions regarding electrostatic parameters was reported. Taking the above mentioned parameters into consideration, predictions and regressions of the distribution to solids shall be improved.

**MO 086**

**The photodegradation mechanism of clofibric acid by UV photolysis**

KD Zoh
Seoul National University, SEOUL, South-Korea

Environmental antibiotic contamination presents the potential to select for resistance factors that can be transferred between bacteria, contributing to the establishment of multidrug-resistant variants. In the present study we have investigated the antibiotic sensitivity pattern of bacterial strains isolated from a treatment plant that receives waste-water from 90 different Indian bulk drug producers. In the treated effluent from this plant, we have previously reported very high levels of antibiotics, predominantly fluoroquinolones, at concentrations up to 1,000,000 times greater than those normally observed in treated sewage effluents. The taxonomic identities of all isolates were determined by 16S rRNA gene sequencing, followed by screening their sensitivity to 39 antibiotics belonging to 11 different classes. All isolates were resistant to, at least, 4 antibiotics, thus conferring a 100% multi-drug resistant population, and the majority were resistant to more than 20 antibiotics. Our study suggests that the waste-water treatment plant studied is potentially serving as an enrichment site for multidrug-resistant bacteria, which could pose a major public health issue in the future.

**Direct and indirect photolysis of the sulfonamide antibiotics sulfapyridine and sulfamethoxazole in Canadian rural wastewaters and surface receiving waters**

CS Wong[1], JK Challis[1], KJ Friesen[1], JC Carlson[1], ML Hanson[2]
[1]University of Winnipeg, WINNIPEG, Canada
[2]University of Manitoba, WINNIPEG, Canada

The direct and indirect photolysis of the sulfonamide antibiotic drugs sulfapyridine and sulfamethoxazole were measured in both controlled laboratory settings and in field waters at Dead Horse Creek, Manitoba, a rural watershed impacted by high nutrient and organic contaminants from episodic pulse releases of effluent from sewage lagoons of the small communities in its watershed. Both drugs degraded quickly in pure water in laboratory when exposed to light simulating natural sunlight, with half-lives ranging from 30 min to several hours depending on the intensity of light used. Abiotic and biotransformation processes for both analytes were insignificant over the time scale of the studies. The absorbance spectra differed for both compounds depending on protonation state, indicating that speciation may affect direct photolysis rates. Measured quantum yields for each species were consistent with previously published literature for sulfamethoxazole. Indirect photolysis increased dissipation rates in field waters, due to the influence of high levels of nitrate and dissolved organic material in wastewaters and surface waters. These results show that natural attenuation by photolytical processes is a major sink of sulfonamide drugs in impacted aquatic systems.

**Investigation of the photodegradation of PDE-V inhibitors and analogues under simulated sunlight by ESI-QqToF mass spectrometry**

J Aceña[1], B Farreira Da Silva[2], PR Gardinali[3], AA Mozeto[2], S Pérez[1], D Barceló[1]
[1]IDAEA-CSIC, BARCELONA, Spain
[2]Laboratório de Biogeoquímica Ambiental, Department of Chemistry, SAO CARLOS, Brazil
[3]SERC, Department of Chemistry & Biochemistry FIU, Biscayne Bay Campus, MIAMI, United States of America

The presence of emerging contaminants in receiving waters is not longer restricted to the environmental assessment of potentially toxic substances, personal care products and prescription drugs. Recent publications are increasingly covering the field of illicit drugs and lately the forensic evaluation of designing illegal analogues of lifestyle drugs like the phosphodiesterase type V inhibitors Viagra (sildenafil), Levitra (vardenafil) and Cialis (tadalafil). Recently, the presence of all three erectile dysfunction treatment drugs has been reported in wastewaters at very low concentrations. In these systems the fate of drug molecules depends largely on their susceptibility to biodegradation and/or adsorption. In the environment, the contaminants undergo various physical or chemical processes classified into abiotic (photolysis, hydrolysis) and biotic (biodegradation) reactions. Thus, changes in the chemical structure lead to the formation of new transformation products (TP), which may persist in the environment or be further degraded. In the present study the photodegradability of Sildenafil, vardenafil, tadalafil and their main human metabolites was evaluated. The reaction was performed under simulated solar radiation using a SUNTEST CPS system equipped with a high intensity xenon lamp. Solutions of each compound in both HPLC grade water and synthetic river water were irradiated for a period of 40 hours. Aliquots of 1 mL of the exposed solutions were withdrawn at regular intervals and analyzed by UPLC-(+)ESI-QqTOF-MS system . sildenafil, desmethylsildenafil, vardenafil, and desethylvardenafil degraded rather easily with half lives in the order of 2 hours for RW. On the other hand, tadalafil degraded with higher half lives (4 hours). The degradation pathway of vardenafil and its metabolite was similar to that of sildenafil and its human metabolite Five TPs were detected for both sildenafil and vardenafil TP393, TP451, TP491, TP382 and TP479. Tadalafil, showed less products than the other compounds investigated with the identified products being TP262, TP428 and TP272. The metabolite demethylsildenafil was also transformed and the main products were TP448, TP450 and TP462.

This work has been supported by the Spanish Ministry of Science and Innovation [projects: SCARCE Consolider-Ingenio 2010 CSD2009-00065]. BFS acknowledges the Capes for the financial support. SP acknowledges the Spanish MEC for the Ramón y Cajal contract

**Removal of diclofenac in conventional drinking-water-treatment processes**

S Rigobello[1], ADB Dantas[2], L di Bernardo[2], EM Vieira[1]
[1]Instituto de Química de São Carlos, Universidade de São Paulo, SAO CARLOS, Brazil
[2]Escola de Engenharia de São Carlos, Universidade de São Paulo, SÃO CARLOS, Brazil

Pharmaceuticals have been widely found in wastewater, surface water and groundwater. This implies a potential for indirect human exposure to pharmaceuticals via drinking water supplies. The conventional methods of water treatment seem to be insufficient to remove these contaminants which vary widely within and among classes of compounds. In this study, jar test experiments were performed with water prepared in laboratory (color of 20HU, turbidity of 70NTU, pH 7.0, diclofenac (DCF) 1mg $L^{-1}$) in order to verify the removal of DCF by coagulation with aluminum sulfate, flocculation, sedimentation, filtration in bench-scale sand filters (clarification) and disinfection (chlorination) . The concentrations of DCF in the studied water samples were determined on a high-performance liquid chromatographic (HPLC) analysis and UV detection, using a C18 bonded silica column (250 x 4.6mm, 5µm). The low rate was 0.8mL $min^{-1}$, injection volume of 20µL, temperature was 25ºC and the wavelength was 270nm. An isocratic mobile phase of acetonitrile (65%) and ultrapure water (35%) was used, both acidified with 0.05% trifluoroacetic acid. The DCF was extracted with C18-E adsorbent (phenomenex), 500mg/6mL, conditioned with 5.0mL of methanol and 5.0mL of ultrapure water. Then, 100mL of water sample were percolated through the adsorbent. Calibration functions, quantification and detection limit, intra- and inter-day reproducibility and accuracy were estimated. The method was successfully applied to determine the drug in water samples of 3 to 1,000µg $L^{-1}$. Removal of total organic carbon (TOC) was also investigated. Results of study indicate wide variability in the effectiveness of each treatment stage. The average percent removal of diclofenac was calculated from water samples collected after filtration and disinfection. The clarification stage not removed diclofenac. The disinfection of the filtered water in bench-scale sand with 5mg $L^{-1}$ $Cl_2$, 0.5 and 24hours accounted for 36.12% and 97% removal, respectively. However, TOC was not removed by clarification and desinfection. The identification of DCF e TOC in finished water indicates incomplete degradation or removal of DCF through the conventional treatment process used in this study and that drinking water can be a source of human exposure to drugs.

[3]UNESCO IHE Institute for Water Education, DELFT, The Netherlands
[4]King Abdullah University of Science and Technology, THUWAL, Saudi Arabia

Dunea, the drinking water company for the Dutch city The Hague and its surroundings, aims to produce drinking water of irreproachable quality, particularly with respect to organic micropollutants. Surface water from the river Meuse is infiltrated and abstracted in the dune areas along the coast. Advanced treatment technologies such as membrane filtration or advanced oxidation are options for additional removal of organic micropollutants. However, the necessity of their application to ensure safe drinking water is still under debate. In addition, most of these techniques have high energy demands. The removal achieved by already existing infrastructure and natural treatment (dune filtration) processes is therefore of first interest and more fundamental knowledge about the underlying removal mechanism is required. In this study, dune infiltration was simulated by batch reactor experiments. The removal of pharmaceuticals was investigated under oxic and anoxic conditions.

Laboratory scale batch reactor experiments were conducted to investigate the removal of 14 different pharmaceuticals during dune filtration. 14 pharmaceuticals were spiked to batch reactors filled with dune sand and water under oxic and anoxic conditions (oxygen concentration below 0.5 mg/L). Samples were taken directly after spiking, after contact times of 10 days and 30 days. Analysis of pharmaceuticals was performed by direct injection of glass filtered samples on UPLC-MS/MS.

Experiments showed that higher removals were achieved under oxic conditions than under anoxic conditions. Ketoprofen and naproxen were almost completely removed under oxic conditions whereas carbamazepine and phenazone were persistent both under oxic and anoxic conditions. The average removal of tested pharmaceuticals was 77%. 12 pharmaceuticals were removed for more than 50% after 30 days under oxic conditions. Under oxic conditions, the removal efficiency was highest between day 0 and 10, whereas under anoxic conditions, the removal efficiency was highest between day 10 and day 30.

**Removal of fragrance compounds from waste water by ozonation and identification of oxidation by-products**

K Bester[1], N Janzen[2], J Hesse[2], E Dopp[2], J Türk[3]
[1]National Environmental Research Institute, ROSKILDE, Denmark
[2]University Duisburg Essen, ENVIRONMENTAL ANALYTICAL CHEMISTRY, Germany
[3]Institute of Energy and Environmental Technology (IUTA), DUISBURG, Germany

A large number of persistent organic pollutants can be found in the effluents of conventional activated sludge waste water treatment plants. Waste water treatment using ozone has been proven as an effective treatment process for a wide spectrum of emerging aqueous organic pollutants. Ozone removes organic contaminants either by direct reaction, or through the formation of OH radicals. However in most cases the pollutants are not removed by complete mineralization, but they are oxidized to by-products. In this study, ozonation of musk and related fragrance compounds in water in the presence and absence of an OH radical scavenger, tert-butanol, was investigated. Mass spectrometrical non-target screening by GC-MS was performed for the identification of oxidation by-products. Oxidation by-products were found, identified and verified in the case of HHCB, while no oxidation products for the fragrance compounds AHTN, OTNE, MX and MK were clearly identified. HHCB-Lactone was identified as a main oxidation product of HHCB. Comparison of the mass spectrum and retention time with a HHCB-Lactone standard verified the finding. In kinetic studies, the required ozone doses needed for the removal of the parent compounds were determined and reaction rate constants were calculated. The reaction was considered pseudo first order as the ozone concentration (5 mg L-1) remained constant as the reaction proceeded. Rate constants for the ozonation of the fragrances in waste water were in the range of 1-100 M-1s-1.

**MO 092**

**Persistence of a human pharmaceuticals cocktail during drinking-water disinfection by chlorine.**

S Mompelat, B Le Bot, O Thomas
Environment and Health Research Laboratory, French School of Public Health, RENNES, France

Human pharmaceutical products (HPPs), so called emerging contaminants, are continuously released into the environment. As numerous studies reported their presence in surface water at the µg/L level and their persistence behaviour to natural attenuation in resource water, the chronic human exposure in mixture at sub-ng/L via DW may hence constitute a potential threat to human beings.
Waste water and drinking water (DW) treatments processes contribute to the decrease of HPPs concentration levels in DW resources and tap water. Nevertheless, few works have already reported the persistence and/or degradation of HPPs during the disinfection process by chlorine, the ultimate step of classic DW supply before entering to the DW distribution network.
In this study, 20 HPPs were selected among the 3000 HPPs released on the market. These 20 target compounds, owning to 11 therapeutic classes (antibiotics, non-steroidal anti-inflammatory drugs, beta-blockers, anti-epileptic, anti-anxiety, antineoplastic, etc.), were chosen particularly upon their already confirmed presence in DW resources and analytical feasibility.
Lab-scale chlorination experiments were performed with the aim to assess persitence of a 20 HPPs mixture upon chlorination at pH 7. Samples of ultrapure water were spiked at 1 µg/L with a mixture of HPPs and 1 mg/L of hypochlorous acid. Chlorination was performed during 18 hours, while the determination of HPPs concentrations in samples was carried out every hour with one single multi-residues method by SPE-UPLC/ESI/MS/MS reaching the ng/L quantification limits.
The results about degradation kinetics of each HPPs will be presented and crossed with results from previous study investigating the occurrence of the 20 target HPPs in real samples of DW. Emphasizing resistant and non resistant HPPs to disinfection by chlorine, these observations will hence contribute to discuss current and future needs as well to improve DW treatment processes to eliminate persistent HPPs from resource water as to focus further efforts on the behaviour of non persistent HPPs during chlorination, possibly involving the formation of unwanted by-products.

**Oxidation of synthetic phenolic antioxidants during water chlorination**

R Rodil, JB Quintana, R Cela
University of Santiago de Compostela, SANTIAGO DE COMPOSTELA, Spain

Antioxidants are substances which prolong the shell-life of foodstuffs by protecting them against deterioration caused by oxidation, such as fat rancidity and colour changes. The most frequent synthetic antioxidants used are the phenolic antioxidants: butylated hydroxytoluene (BHT), butylated hydroxyanisole (BHA) and *tert*-butylhydroquinone (TBHQ). These compounds have been detected in river, ground and wastewater samples. Levels of these compounds were typically in the 10- 2000 ng $L^{-1}$ range, depending on the sample nature. Moreover, their degradation products should also be evaluated since they may pose an environmental or human health risk.
Thus, the aim of this work was to study the chlorination of phenolic antioxidants and some metabolites, bearing in mind that, according to the European Federation of Chlor-alkali Producers, 98% of the DWTPs in Europe use chlorination as one of the main disinfection steps in drinking water production and is sometimes used for tertiary treatment of wastewater. Gas chromatography-mass spectrometry was used to follow the time course of the antioxidants and by-products, and also used in the identification of the by-products. Under strong chlorination conditions (10 mg $L^{-1}$ chlorine, 24 h), five of the target compounds were significantly degraded, while only BHT-Q (2,6-di-*tert*-butylcyclohexa-2,5-diene-1,4-dione) and BHT-CHO (3,5-di-*tert*-butyl-4-hydroxybenzaldehyde) were stable. The addition of bromide to the sample was negligible, but for BHA, where an increase in the degradation rate was observed. Moreover, the degradation kinetics were investigated at different concentrations of chlorine and pH of sample by means of a factorial experimental design. It was observed that the pH of the sample was a significant factor for BHT and BHA, and chlorine concentration was significant for BHT, resulting in increased degradation kinetics as they are increased. The degradation of these compounds has revealed two main processes: hydroxylation and oxidation of the aromatic system. The by-products were investigated in real samples (surface and waste water) by SPE-GC-MS.

**Generation, assessment and affinity purification of a broad-specificity high titre antiserum to penicillins using 6-amino-penicillanic acid as a hapten**

LK Kantiani[1], RA Abuknesha[2], MU Farré[1], DC Barceló[1], DC Barceló[3]
[1]IDAEA-CSIC, BARCELONA, Spain
[2]School of Biomedical & Health Sciences, King's College London, LONDON, United Kingdom
[3]Catalan Institute for Water Research (ICRA), GIRONA,, Spain

Penicillins belong to the group of β-lactam antibiotics and are most widely used in veterinary medicine for treatment of bacterial infection, or to serve preventive and prophylactic purposes. They are also provided illegally as supplements in feed stuffs to promote growth of food-producing animals. Therefore, control of penicillin residues in milk is a major issue since the have been reported to cause allergic reactions and carcinogenicity. In addition, continuous presence of the antibiotics in heavily consumed foods is thought to promote of the spread of bacterial resistance to the valuable antibiotics used in human medicine.
The aim of this study was to determine optimal conditions for penicillin determination in milk by means of an enzyme-linked immunosorbent assay (ELISA). A polyclonal antiserum to penicillins was generated in sheep using maleimide-caproic acid-6-aminopeniccillanic acid derivative coupled to thiolated KLH as immunogen. Plate coating antigen conjugates of 6-aminopenicillanic acid or ampicillin and gelatine were prepared using cyanuric chloride as a linking bridge. Indirect competitive assays were developed to assess the antiserum, potential performance of the assays. However, in order to improve specificity and detection limits and reduce assay time (direct competitive assays), the polyclonal antibody was purified by means of antigen-based affinity chromatography in which bound antibodies were eluted with a mixture of acetonitrile and propionic acid from Sepharose 4B-hapten gels. ELISA tests were used to monitor the absorption and elution and assess the degree of structural and functional purity of the isolated antibody preparations. Finally, the affinity-purified antibody was labelled with horseradish peroxidase using cyanuric chloride as a bridging molecule.
ELISA assessment of the labelled antibody showed very high antibody activity (high titre) and coupling of over 80% of the enzyme. The direct competitive assay developed for detection of penicillins was applied in serum and centrifuged milk, with minimum detection value in the region of 10 ng/mL and a dynamic range of 10 ng/mL to 25 µg/mL. Assessment of the competitive ELISA response to various penicillins and other groups of antibiotics showed high degree of response to all tested penicillins (100%) but no detectable cross reactivity with any of the commonly used non-penicillin compounds including tetracycline, sulphonamides, macrolides, cephalosporines and fluoroquinolones.

## EH02 - Monitoring and modeling stressed ecosystems to support ecosystem-based management

**MO 098**

**Urban environmental zoning depending on industrial loading for environmental monitoring and spatial planning**

V Zaitseva, V May
Federal Centre for Medical and Preventive Health Risk Management Technologies, PERM, Russian Federation

Perm is a large industrial city situated in the western Ural Mountains, Russia, where several dozens of oil-refining, petrochemical and metal-working enterprises, power facilities, mechanical etc. are located. During a long period of time the urban environment has been exposed to complex anthropogenic pollution. Abiotic factors, in particular the composition of air, soil, environmental waters, have led to significant urban ecosystem degradation.
The Perm citizens, as an integral part of the urban environment, are also exposed to anthropogenic environmental pollution.
In order to develop the General Plan and improve the whole urban spatial planning system, the city area was divided into nine zones wherein the levels of anthropogenic loading appear to be the highest and most critical. These are the main principles of urban spatial planning aimed at reducing environmental loading:
- optimal restriction of production facilities, i.e. sources of adverse impact, to well-defined industrial areas;
- meeting the standards of sanitary protection zones around industrial hubs;
- locating production facilities outside dwellings areas or performing the conversion of industrial enterprises having hazardous impact on the urban system;
- locating new production facilities within the city area provided that they utilize exclusively low-waste technologies meeting the highest technological and equipment standards;
- making maximum use of the natural potential of green spaces, the city forests and other areas for natural environmental self-cleaning and restoration.

The General Plan includes a green belt composed of minor river valleys reorganized into recreation zones around the central part of the city. It also stipulates that sanitation and environmental rehabilitation measures including water bodies' treatment, soil reclamation, and flora improvement should be taken within a number of city districts.
It was determined that the pollution levels in industrial zones could be also reduced by thickening barrier vegetation with the density of such green belts will be from 800 to 1000 trees and 1500 - 2200 bushes per hectare depending on the composition peculiarities of a given territory.
In conclusion, urban environmental zoning depending on industrial loading for environmental monitoring and spatial planning allowed the identification of priority zones that require restoration and the development of the most efficient measures aimed at environmental improvement.

**Heavy metals and their chemical forms in eroded soils**

TG Leah
Institute of Pedology, Agrochemistry and Soil Protection "N.Dimo", CHISINAU, Moldova

Matrix population models are some of the most widely used models by population biologists. They are easy to construct and understand, but are they a good choice for use by ecological risk assessment of chemicals? Here, I discuss the strengths and weaknesses of matrix models as a tool for ecological risk assessment using models developed for a number of organisms exposed to pesticides. Results of this study indicate that matrix models are a good choice for an initial screening of toxicant effects because multiple effects (lethal and sublethal) can be easily incorporated into these models, they are easy to develop, use, and to understand. Therefore, matrix models should be the first choice for an initial risk assessment.

**MO 100**

**An integrated modeling framework for decision support in ecosystem-based management: case study Lofoten/Barents Sea**

J Carroll[1], MGD Smit[2]
[1]Akvaplan-niva, TROMSØ, Norway
[2]Statoil, TRONDHEIM, Norway

Ecosystem based management is today the foundation of international regulatory frameworks for managing the oceans and seas. The approach enables sustainable use of marine goods and services while maintaining good environmental status and preventing subsequent deterioration. Standard methods for regulatory risk assessment are based on precautionary principles and worst case assumptions. Although these methods are useful for environmental management and risk mitigation for the petroleum industry, they have limited value in ecosystem-based management approaches where comparative risk/benefit assessments are essential. To support ecosystem based-management, models should be developed that simulate in more realistic detail the marine biosphere and focus on the prediction of actual potential impacts instead of worst-case risks. Today we lack holistic models capable of supporting ecosystem based management decision-making.
To resolve this problem, an international consortium of petroleum industry partners has established a project to develop an integrated modeling framework for ecosystem based impact assessments of the marine environment. An integrated modeling framework will be developed including an ecosystem and ecotoxicology module, which integrates existing ecosystem models for adult fish, fish eggs & juveniles, phyto- and zoo- plankton, chemical fate and ecotoxicology. Development of the integrated modeling framework involves experts in ecology, ecotoxicology, risk assessment and modeling from 16 institutes and 8 nations.
The framework is initially being developed for applications in the Lofoten/Barents Sea to address the combined effects of fisheries and petroleum activities. The region is rich in petroleum resources and is also characterized as a key spawning and egg and larval drift areas North Atlantic commercial fish species. Here we describe the model system and developmental process and show how such approaches are of value toward providing stakeholders with more quantitative information on the environmental risks and benefits of petroleum development activities in potentially contentious areas.

## MO 101

**Combined use of environmental data and biomarkers in Liza aurata from a eutrophic and metal-contaminated coastal lagoon (Óbidos lagoon, Portugal)**

P Pereira[1], H de Pablo[1], C Vale[1], M Pacheco[2]
[1]Instituto Nacional de Recursos Biológicos (INRB/IPIMAR), LISBOA, PORTUGAL, Portugal
[2]CESAM/Departamento de Biologia da Universidade de Aveiro, AVEIRO, Portugal

An investigative biomonitoring study was carried out in a eutrophic coastal system with a moderate contamination by metals (ð'bidos lagoon, Portugal). The selected approach combined the evaluation of field exposure levels (metals and nutrients) with metals accumulation and oxidative stress responses in gills of the fish Liza aurata. Two contrasting seasons (winter and summer) were considered at three sites: Barrosa (BB) and Bom-Sucesso (BS) inner branches; Middle lagoon (ML). Data on water column pointed to a higher metals and nutrients availability at BB site that was reflected in the higher metal contents in gills, particularly in winter. Similarly, oxidative stress responses demonstrated a pro-oxidant challenge at BB (winter and summer), being substantiated by a general stress index (IBR). Gills' metals load was higher in summer than winter, explained by the increased environmental concentrations in combination with elevated metabolic rates. Catalase (CAT), glutathione-S-transferase (GST), total glutathione (GSHt) and lipid peroxidation (LPO) increases observed in winter at BB were related with metal accumulation. Conversely, summer enhancements of GPx, GR, GST and GSHt were associated with other stressors. Inter-site differences on the basis of IBR were more accentuated in winter. The applied approach combining biomarkers in gills and environmental data demonstrated to be useful in the environmental health assessment, particularly under a moderate contamination scenario. Gills can be considered as a "mirror-door"in the context of water contamination assessment, based on its confirmation as an important route of entry for contaminants and the currently demonstrated ability to reflect environmental health status.

## MO 102

**Benthic fauna indicates chemical sediment quality**

D de Zwart[1], L Posthuma[1], JF Postma[2], AJG Reeze[3], L Osté[4]
[1]RIVM, BILTHOVEN, The Netherlands
[2]Ecofide, WEESP, The Netherlands
[3]Arcadis, APELDOORN, The Netherlands
[4]Deltares, DELFT, The Netherlands

The European Water Framework Directive (WFD) defined a suite of chemical and biological quality elements and yardsticks to demonstrate Good Ecological Status (GES). The yardsticks are designed such that in case of deviations from GES, they also indicate potential causative factors. In the Netherlands, recently a new biological yardstick was developed to indicate chemical sediment quality in type R8 tidal fresh water systems (lowland river estuaries) by evaluating local assemblages of taxa of benthic fauna communities. Further insights into the R8 yardstick and its meaning were obtained by applying two techniques. Firstly, the concept of toxic pressure quantification for mixtures was applied, replacing the originally used per-compound concentration data. The toxic pressure concept quantifies which fraction of the species is likely affected by a local mixture of toxicants. Secondly, focus was put on the abundance of separate taxa in relation to a potential suite of stressors, among which the toxic pressure of chemicals. The results showed that the acute toxic pressure of the local mixtures in the study area varied between 0 and 42%. Chronic toxic pressure varied between 0 and 76%. These findings imply that the local toxicity of mixtures is likely to affect local species composition. Furthermore, it was demonstrated that toxic pressure is highly significantly related to variations in abundance in 74% of taxa. It was observed that the earlier proposed R8 classification in groups of indicator taxa, based on multi-variate patterns in response to toxicant exposure is largely, but not fully reflected in the taxa specific sensitivity towards toxicant mixtures. Finally it is concluded that increasing sediment toxicity is related to increasing effects, both on taxon richness and abundance.

Diatoms play a key role in the functioning of streams, and their sensitivity to many environmental factors has led to the development of numerous diatom-based indices used in water quality assessment. Although diatom-based monitoring of metal contamination is not currently included in water quality monitoring programs, the effects of metals on diatom communities have been studied in many polluted watersheds as well as in laboratory experiments, underlying their high potential for metal contamination assessment. Here, we built large database of river diatoms (comprising more than 600 taxa) that were exposed to various loads of heavy metals in the water was investigated. The samples were collected during field surveys carried out in 6 different countries (France, Spain, Switzerland, Canada, Vietnam, China). After taxonomy harmonization, the patterns in diatom community structure were investigated for 202 samples, all collected from hard substrates in rivers with circumneutral water pH. As the sites were contaminated by a mixture of different metals (mainly Al, As, Cd, Cr, Cu, Fe, Hg, Ni, Pb, Zn) with various loads, metal concentrations were converted into a single score after Clements et al. (2000) in order to classify sites according to potential metal toxicity. Metal contamination proved to be a strong driver of the community structure, and enabled for the identification of tolerant species like *Eolimna minima*, *Surirella angusta, Cocconeis placentula* var. *euglypta* or *Pinnularia parvulissima*. Traits were also tested: diatom cell size and the occurrence of diatom deformities were found to be good indicators of high metal contamination. This work provides a basis for further use of diatoms as indicators of metal pollution.

## MO 104

**Background concentrations of POPs in the Arctic: a risk assessment**

J Hammer[1], K Soetaert[2], CR Janssen[3], F de Laender[3]
[1]University of Amsterdam, AMSTERDAM, The Netherlands
[2]NIOO - CEME, YERSEKE, The Netherlands
[3]Ghent University, GHENT, Belgium

Persistent organic pollutants (POPs) are present in all oceans and the Arctic Ocean in particular accumulates POPs due to northward sea and air currents. Although there are extensive databases that contain field measurements of POP concentrations in Arctic species, they represent a haphazard collection of measurements in various tissues and species. This hampers a standardized quantification of the risk of POPs for Arctic ecosystems. In this study we quantify, for the first time, the ecological risk caused by background concentrations of all POPs measured in the Arctic Ocean between 1985 and 2010. A bioaccumulation model was used to standardize >49.000 measured concentrations in different matrices of various species to lipid tissue concentrations of 96 POPs (PCBs, HCHs, HCB, DDTs and PAHs) in 26 species ranging from northern shrimp (Pandalus borealis) to the polar bear (Ursus maritimus). After cross-validation of predicted tissue concentrations, they were combined with QSAR estimates of no observed effect concentrations to predict the risk quotients (RQs) for all 96 chemicals in all 26 species. The RQs of all substances in all species decreased over time (between -2.48 [GREEKX] 10-7 y-1and -9.46 [GREEKX] 10-7 y-1) with the exception of PAHs which increased (between 1.36 [GREEKX] 10-7 y-1 and 5.32 [GREEKX] 10-6 y-1). The highest RQ was found for fluoranthene in polar bear (Ursus maritimus) in 2010 (1.37 [GREEKX] 10-4). Assuming concentration-addition toxicity of the 96 chemicals, the total RQ increased on average twofold between 1985 and 2010 with current day total RQs varying between 2.48 [GREEKX] 10-4 for fish larvae and 9.29 [GREEKX] 10-4 for polar bear.

## MO 105

**Using river metabolism monitoring to quantify sediment budgets in river stretches**

T Gallé
CRP Henri Tudor, ESCH-SUR-ALZETTE, Luxembourg

Sediments play an important role in river ecosystems as a food source and pollutant mediator: they can figure as pollutant sinks but can also transfer these pollutants to the food web if the sediments serve as subsidy and the pollutants are bioavailable. Hence it is important to quantify the dynamics of sediment budgets and their quality during the seasons. As rivers are hydrologically dynamic and sediment deposits very patchy, representative samplings are an unresolved challenge in sediment research. This poster presents a method relying on the well established river metabolism introduced by Odum, which allow for the calculation of Gross Primary Production (GPP) and Ecosystem Respiration (ER) in river stretches from continuous oxygen recordings. In addition sediments were re-suspended in a dozen spots in these 200 m long stretches and analyzed further in the laboratory. The main parameter investigated was the 24h Biological Oxygen Demand (BOD) of the sediment samples which is related to organic carbon content and other parameters reflecting the lability of the organic matter (chlorophylls, sugars, phospholipids). This poster shows the dynamics of metabolism parameters and sediment characteristics over one vegetative season in two differently polluted Luxembourgish rivers and proposes a method to quantify the sediment budgets by relating BOD and ER measurements.

## MO 106

**Effects of ocean acidification on marine bacterial communities**

CH Johansson, T Backhaus, H Blanck, S Brosché, KM Eriksson
University of Gothenburg, GÖTEBORG, Sweden

Decreased pH in our oceans is of great concern and effects have been shown on marine calcifying organisms. Still, more effects are to be expected on other organisms and parameters as well. Additionally, different organisms interact with each other in complex ways and the loss of a few species might have drastic effects on many organisms indirectly. This dictates the need to evaluate effects also on the community level. Long-term effects of lowered pH on marine periphyton communities were studied in a flow-through microcosm system. The periphyton was established from the indigenous microbiota in natural seawater from the Gullmar fjord on the Swedish west coast. Acidification to pH 7.7±0.07 was achieved with a pH-stat set up regulating the intermittent inflow of carbon dioxide. pH of the control aquaria fluctuated between 8.4 and 8.1 according to the actual pH of the fjord water. Several ecotoxicological endpoints (genetic profiling, trace elements profiles, leucine incorporation and bacterial catabolic profiling) were used to assess a broad range of effects on periphyton (see contribution by Eriksson et al., same session). This poster reports on the impact of acidification on total bacterial activity (incorporation of radiolabeled leucin), community genetic structure (PCR-TGGE) and on community function (catabolic profiles using Ecolog plates). Acidification led to an increased catabolic activity with respect to 12 out of the 31 carbon sources in total, four of them were affected severely. This indicates that lowered pH induce a shift in community structure and function.

## MO 107

**Fish liver structural changes as biomarkers to assess stream water quality in Jales Mine area (Portugal) - preliminary data**

S Carrola[1], E Rocha[2], A Gomes[1], M Monteiro[3], A Coimbra[3], V Ferreira-Cardoso[3], S Varandas[1], M Araújo[1], A Fontaínhas-Fernandes[3]
[1]UTAD, VILA REAL, Portugal
[2]ICBAS/CIIMAR, PORTO, Portugal
[3]CITAB and ECVA, UTAD, VILA REAL, Portugal

Water ecosystems are suffering a worldwide increasing pressure caused by anthropogenic activities, including mineral extraction and mineral processing, which affect direct or indirectly all aquatic organisms. In some cases the abandon of mine activities led to serious environmental problems linked to tailings pollution, like it occurred in Jales Mine in 1992. In 2006 the tailing area was re-qualified in order to solve serious environmental and public health problems. We have been monitoring the local ecosystem using fish, and particularly hepatic changes/lesions, before and after the mitigation project, continuing a previous study published by our group (Carrola et al., 2009).

The principal aim of the current approach is to maintain an assessment of the stream closed to the abandoned Jales Mine using wild fish, namely Chondrostoma polylepis duriensis and Salmo trutta fario. For such purpose, we continued to survey liver histopathology, now integrating other bioindicators such as macroinvertebrates.

Fish were caught in September 2010, by electroshocking, in the same points used in the previous monitoring: upstream, the reference site (FB) and downstream the Jales Mine tailing zone, namely Peliteira-Tinhela (PT), Murça (MU) and Reboredo (RE).

Two main types of histopathological lesions were observed, namely hepatocytic necrosis and

lymphocytic hepatitis. Just in one fish, there was slight vacuolation of liver cells. No severely vacuolated hepatocytes, basophilic cell foci, bile duct hyperplasia, epithelial dysplasia and fibrotic adventitial sleeve, were observed, contrary to those reported in the 2009 study.
We concluded that in 2010 the liver histopathology disclosed no substantial differences among upstream and downstream fish. Moreover, the fish presented lesser quantitative as well as qualitative hepatic lesions when compared with the previous study performed in the same points, thus suggesting an improvement in water quality after the environmental re-qualification project.

**Monitoring predatory mite populations in the field: validation of assessment tools**

FM Bakker[1], L Hartman[2]
[1]MITOX Consultants, AMSTERDAM, The Netherlands
[2]University of Landau Koblenz, LANDAU, Germany

Predatory mites provide for an important component of plant protection services in various agro-ecosystems. Adequate monitoring of predatory mite populations is therefore key to exploit this service optimally. We have validated and cross compared three monitoring tools that are currently widely used for use in orchard and vineyard systems. In all cases leaves were detached before counting started. We compared direct counting on detached leaves and counting following extraction of the mites from the detached leaves. The extraction was performed through Berlese extraction and through washing of the leaves. Following extraction the solution containing the mites was transferred to a counting device that could be placed under the binocular microscope. The three techniques were found to differ importantly in their accuracy and their sensitivity to uncontrolled variation in operator handling.

**MO 109**

**Degree of population level effect of multiple stress depends on exposure interval in relation to life history and seasonal phenology**

FM Bakker, J Roig
MITOX Consultants, AMSTERDAM, The Netherlands

Predatory mites provide for an important component of plant protection services in various agro-ecosystems. Depending on species, crop and region typical phenologies differ. We investigated how, following exposure to insecticidal stressors, the capacity to return to levels of undisturbed populations might relate to the underlying life history and the resulting seasonal phenology. We studied two agroecosystems, both typical for the southwest of France. Amblyseius andersoni is a predatory mite abundant in orchards. It overwinters as adult on the weeds under the trees and returns to the trees in spring when the buds open. Typhlodromus pyri is a predatory mite common in vineyards. It overwinters on the vines, and starts populating the green part of the plant when the buds break. In both cases populations are first composed of adult females only, which is followed by a phase where larvae dominate the age distribution. As the season progresses the density per leaf increases and the age distribution stabiles and the density of mites per leaf reaches a plateau. Because apple trees have an earlier development than vine, the mite populations on these crops also have a different seasonal phenology. Effects of insecticidal stressors were found to vary with life history characteristics of the species involved and with the timing of the exposure.

**Microtox - Transformation, bioaccumulation and toxicity of organic micropollutants in the Yangtze Three Gorges Reservoir**

A Schaeffer, HH Hollert, MRN Roß-Nickoll, BS Schmidt, RO Ottermanns, BSS Scholz-Stark, YY Yuan, TF Floehr, KS Strauch
RWTH Aachen University, AACHEN, Germany

The Three Gorges Dam is one of the great projects that enduringly change Chinas nature. Its Reservoir covers a total area of ca. 1085 km2 of the Yangtze river in a total length of 663 km. The creation of the reservoir caused the flooding of former urban, industrial and agricultural areas. This caused a release of substantial amounts of organic and inorganic pollutants into the reservoir. Beyond contaminants and nutrients (e.g. nitrate, phosphate) enter the reservoir by runoff from adjacent agricultural areas as well as from sewage of industry, aquacultures and households. Periodical changes in water level cause flooding events and thereby a relocation of contaminated water, particulate matter and sediment onto agriculturally used areas along the reservoirs shore. The Three Gorges Reservoir and its surrounding area is the source of food and water for plenty of people. Based on these risks for the population and to preserve this newly created ecosystem is it of importance to develop techniques and procedures that sustainably limit the emission of contaminants into the reservoir.
The recent project is undertaken within the joint research framework "Sustainable Management of the Newly Created Ecosystem at the Three Gorges Dam (YANGTZE-PROJECT)"(www.yangtze-project.de) financed by the Federal Bureau of Education and Science (BMBF) as part of the research cluster "Pollutants / Water / Sediment - Impacts of Transformation and Transportation Processes on the Yangtze Water Quality". The joint project is carried out in cooperation with numerous German and Chinese partners.
Aim of the presented project is to elucidate the fate (Module 1), potential of bioaccumulation (Module 2) and ecotoxicological properties of major Yangtze pollutants to indigenous organisms (Module 3).Overall objective is to develop a monitoring strategy to evaluate the degree of pollution and identify pollution hot spots in the Three Gorges Reservoir. Beyond may these findings serve as a starting point for a subsequent project on management strategies to reduce the pollution in temporary Yangtze flooding areas.

**MO 111**

**Long-term effects of lowered pH on marine periphyton communities**

M Eriksson, H Johansson, H Blanck, T Backhaus, S Brosché, S Dupont
University of Gothenburg, GÖTEBORG, Sweden

The phenomenon of Ocean Acidification has been identified as a potential threat to several marine organisms and might lead to adverse disturbances of marine ecosystems. Although the knowledge about effects of rising acidity in the oceans is increasing for some species, the knowledge of these effects on the community level of biological complexity is very scarce. Still, community-level effect indicators are needed in order to predict direct and indirect effects of Ocean Acidification on marine ecosystems. In a community the organisms live in their realized niche with important ecological interactions (e.g. competition, grazing and predation) present. This gives community approaches in ecotoxicological tests high ecological relevance. Since lowered pH might eliminate species or strains that are sensitive to such stress, and select for the ones that are more competitive under this condition, a community approach have the potential to detect any pH-induced change in community structure or function. We have used marine periphyton communities in a long-term study of effects of increased partial pressure of CO2 in the water and the accompanied lowering of pH. Periphyton was allowed to colonize and grow on glass substrata for 3.5 weeks in flow-through microcosms. The pH in the microcosms was either that of the incoming natural surface water or was manipulated by bubbling of CO2 down to approximately 7.7. We used Pulse Amplitude Modulation (PAM) to detect effects on photosynthetic electron transport and estimate induced community tolerance to low pH. In addition, we used confocal microscopy to trace effects on biofilm architecture and biofilm thickness. We have also estimated microbial diversity and composition of trace elements in periphyton using PCR-TGGE and X-ray fluorescence respectively. First results indicate that long-term effects of lowered pH change the capacity of communities to tolerate further changes in pH, making them more sensitive to pH-stress. However, no long-term effects on photosynthetic electron transport or trace element composition was detected.

**MO 112**

**Linking the individual to community levels: a place for arthropod molting enzymes in ecotoxicology?**

ML Hanson[1], A Sastri[2]
[1]University of Manitoba, WINNIPEG, Canada
[2]Université du Québec à Montréal, MONTREAL, Canada

Chitobiase is one of two molting enzymes (the other being chitinase) used to cleave chitin polymers that comprise the exoskeleton of aquatic arthropods. Following molting this enzyme is released into the water and can be quantified by a simple fluorescence assay. The standing activity and it's rate of production has been used as a measures of: 1) secondary production rates; 2) moulting rates; and 3) developmental biomass for entire crustacean zooplankton communities under laboratory and field conditions; and 4) responses to some contaminants in zooplankton and crustaceans. Yet, despite its relative methodological ease, chitobiase has only been used sporadically as an ecotoxicological tool to monitor and quantify changes in secondary production as a result of exposure to a stressor(s). In this paper we reviewed all the available literature pertaining to the use of chitobiase as a measure of stressor response and make the following recommendations for future research: 1) current methodologies be further validated, e.g., quality assurance and quality control measures be adopted, enzyme storage conditions and times be experimentally confirmed; 2) that the variation in activity relative to life history stage and/or body size for different taxonomic groups be characterized in order to examine the impact of stressors in laboratory-based studies and the utility of the approach as a field-based measure of community-level processes; and 3) the response of selected organisms be characterized for model stressors to confirm the utility the observed responses relative to more traditional endpoints, e.g., reproduction and growth. Overall, the use of chitobiase has enormous potential as a tool in ecotoxicology, but extensive groundwork and validation is still required before it can be widely adopted.

**Characterization of kidney histology in tilapia (Oreochromis niloticus) as biomarker tool for fish health assessment - preliminary data**

MJ Peixoto[1], JV Ferreira-Cardoso[2], JS Carrola[2], MJ Pires[3], A Fontaínhas-Fernandes[2]
[1]UTAD, VILA REAL, Portugal
[2]CITAB and ECVA, UTAD, VILA REAL, Portugal
[3]DCV and CECAV, UTAD, VILA REAL, Portugal

Human activities have resulted in environmental pollution worldwide, by releasing different kind of chemical compounds. These pressure affects water availability and quality, in most cases unsuited for the desired use. But have also serious effects on all living organisms, including animal and human health.
Biological monitorization make use of histological biomarkers, among others, integrated in a multidisciplinary approach, as a complement to classical physical and chemical monitoring parameters. Thus, several organs can be used for this purpose like fish kidney and normal histology knowledge is essential. Field and laboratory studies have established a causal relationship between fish pathology and levels of pollution.
Fish kidney can be divided in two main regions, the anterior (or head kidney), composed of hematopoietic tissue, lymphoid tissue and cells with endocrine function, and the posterior (or trunk kidney), composed of renal parenchymal tissue, whose functional unit is the nephron, which plays an essential excretory function.
This work is centered on the study of tilapia kidney ultrastucture and histology (anterior and posterior regions) to apply that data for future studies, as a complement to other organs histopathology.
After being euthanized with 2-phenoxyethanol, tissue samples were collected from the anterior and posterior part of the kidney of 7 male fishes, and fixed with formaldehyde. Then sections were cut (5 μm) and stained with H&E. After that, slides were examined by light microscopy.
Preliminary data show that the anterior kidney region of tilapia is constituted mainly by interrenal cromaffin and lymphoid tissue, as well as melanomacrophagic centers (MMCs) while in the posterior region we found renal corpuscles with well developed Malpighi glomeruli, Bowman's capsule with two layer (visceral and parietal) and Bowman's space, and a conspicuous system of tubules (proximal, distal and collecting) as found in other fish species.
We also observed differences in cellular organization of the kidney, related with age and degree of sexual maturation of fishes.
This study was focused in histological characterization of tilapia kidney and may constitute a basic support for future studies for assessment of histopathological lesions/alterations in fish kidney exposed to chemical compounds.

**The flood-prone transport of historical contaminants to the Elbe Estuary: modelling their deposition and monitoring their effects on the ecosystem**

S Heise[1], J Angelstorf[1], P Hsu[1], KL Moshenberg[1], A Schulte-Rentrop[2], H Weilbeer[2], N Winkel[2]
[1]Hamburg University of Applied Sciences, HAMBURG, Germany
[2]Federal Waterways Engineering and Research Institute, HAMBURG, Germany

High discharge conditions in the Elbe river lead to resuspension of highly contaminated sediments in the up-stream part of the Elbe catchment, the most contaminated areas being in the Czech Republic, in the catchments of the tributaries Mulde, Saale (about 300 km upstream of Hamburg), and probably in the groyne fields in between. While we are currently modeling the contaminant transport along the major river (see Moshenberg, SETAC-Europe 2009), the area of the Elbe estuary still is a big challenge: The tidal impact along with dredging activities of the river and a large turbidity cloud, drifting back and forth in the estuary, all lead to a complex sedimentation pattern in an area where nature reserves are in close proximity to the second largest harbor in Europe.

This poster describes the results of several event-based sampling surveys carried out over 2 years, describing the ecotoxicological and chemical effects of flood-induced transport of contaminants to the estuary from the Hamburg area to the mouth of the river. Applying a hydrodynamic 3-dimensional model that has been developed by the Federal Waterways Engineering and Research Institute over years for the Elbe estuary, we interpret those data on the basis of projected transport pathways and sedimentation patterns of relevant contaminants in the tidal Elbe area comprising nature reserves, harbor basins, beaches, fishing grounds and urban environments. Together with assessment of contaminant loads, carried downstream by flood events, and climate change projections, temporal development of the contamination pattern in the Elbe will be discussed.

**MO 115**

**Assessing the impact of watershed land use on aquatic biodiversity over large spatial scales using benthic macroinvertebrates.**

E Cummings, MD Matlock
University of Arkansas, FAYETTEVILLE, AR, United States of America

Data from the United States Geologic Survey (USGS) North American Water Quality Assessment (NAWQA) and the United States Environmental Protection Agency (EPA) Wadeable Streams Assessment (WSA) were used in an attempt to identify correlations between land use parameters and a measure of aquatic biodiversity at large spatial scales. Data from the USGS NAWQA program included multiple years of sampling at single sites, ranging from 1993 to 2008. Data from the EPA WSA study included many more sites but only from a single year. Results from the assessment show correlations between measures of aquatic biodiversity and forest land use (positive correlation) and urban land use (negative), but fail to show a correlation between agricultural land use and aquatic biodiversity. This outcome agrees with other studies on the impact of anthropogenic land use and water quality, indicating a much stronger influence of urban systems. Though the influence of urban land use appears to be much more pronounced than agricultural land use, this does not mean that agriculture does not impact aquatic biodiversity. Instead it suggests that under specific conditions and proper management practices agricultural land use has a lower threat potential than urban land use. This gives hope to the prospect of reducing the impact of urban land use through use of management practices similar to those currently employed in the agriculture sector.

**High frequency aquatic ecosystem biomonitoring**

F Pomati[1], BW Ibelings[2], M Simona[3], M Veronesi[3], J Jokela[1]
[1]Eawag, KASTANIENBAUM, Switzerland
[2]NIOO, NIEUWERSLUIS, The Netherlands
[3]SUPSI, LUGANO, Switzerland

In world threaten by multiple anthropogenic impacts, innovative approaches to lake-ecosystem monitoring and assessment of lake ecosystem functions are required for a correct management of water resources, the biodiversity that they harbor and the services that they deliver. We developed an innovative and potentially ground-braking tool for high frequency monitoring of lake phytoplankton. We have designed a lake monitoring platform for the characterization and counting of algal cells (based on scanning flow-cytometry), coupled with measurement of the physical water environment (multiparameter probe). The aims of our technology are to monitor automatically and with high frequency the vertical profile of the water column for phytoplankton diversity, composition and abundance, functional traits, and physico-chemical parameters. The platform performed its first monitoring program in full functional mode in May 2010 in Lake Lugano (Switzerland). Data were collected with a frequency of 2 vertical profiles of the water column per day. Automated data were coupled by fortnightly independent measurements of physico-chemical characteristics of the water column and phytoplankton for an assessment of the actual capabilities of our technology. Results of our automated platform were comparable with traditional monitoring data. Our description of phytoplankton diversity patterns offered levels of statistical reproducibility, depth resolution and high frequency that are unachievable with traditional limological campaigns. Additionally, our functional classification of organisms and the real-time measurement of morphological traits hold the potential of increasing our ability to explain the organization and predict the reorganizations of the community under applied stressors. Our automated time-series of high frequency data offers novel opportunities for tracking, understanding and modeling changes in aquatic biodiversity and its drivers at the community level. Identification of drivers of community diversity and the effects of diversity on ecosystem functions is expected to lead to a better understanding of the adaptive potential and resilience of an aquatic ecosystem to change.

**Origin, source, exposure and toxicology of Non-Aroclor PCB11**

C Hornbuckle, D Hu, RF Marek, A Martinez, HJ Lehmler, PS Thorne, X Hu, D Spitz, Y Zhu, N Aykin-Burns, S Flor, G Ludewig, L Robertson
University of Iowa, IOWA CITY, United States of America

Despite being a member of one of the most regulated compounds in the world, PCB11 (3,3'-dichlorobiphenyl) is a virtually uncontrolled global pollutant. It was not produced in significant quantities as a component of commercial mixtures of polychlorinated biphenyls (PCBs) and therefore was not subject to the scientific attention paid to many PCB congeners. However, the compound has been reported in air and wastewater around the world. Here we summarize our current knowledge of the sources, environmental history, and toxicologic effects of PCB11.
We recently reported that PCB11 is produced inadvertently during the manufacturing of commercial paint pigments and we have hypothesized that this production explains the presence of this compound in air and water around the world, including urban centers like Chicago and Philadelphia and remote regions of the Great Lakes and in the Arctic. Although the presence of PCB11 in the environment was only recently detected, the history of environmental exposure dates back at least 70 years. Using dated sediment cores from the Great Lakes, we have found that North American environmental exposure to PCB11 began to increase in the 1940s through the 50s and accelerated until the early 1980s before falling back to 1950s levels where they remain now.
Because PCB 11 is not among the PCBs commercially produced, the hazards associated with this long period of environmental exposure are poorly known. Our laboratories are currently evaluating the toxicity of PCB11 and initial studies show that PCB11 is a weak endocrine disrupter and demonstrates little cyto- and geno-toxicity in cultured mammalian cells. However, its putative primary hydroxylated metabolite 3,3'-dichlorobiphenyl-4-ol induced significant clonogenic cell killing as well as increased reactive oxygen species in exponentially growing immortalized human prostate epithelial cells. In addition, treatment with superoxide dismutases and catalases after 4-OH-PCB11 exposure significantly protected the cells from PCB toxicity. These results strongly supported the hypothesis that exposure to a metabolite of PCB11 can inhibit human cell proliferation and cause cytotoxicity by increasing the reactive oxygen species that can be mitigated with antioxidant treatments following PCBs exposure. Additional studies evaluating the toxicity of PCB11 and its metabolic progeny are ongoing.

**MO 124**

**PAH release from rubber granulates of artificial turf fields: preliminary hazard assessment for the athletes**

D Coppola, MC Fossi, S Maltese, L Marsili
University of Siena, SIENA, Italy

Nowadays synthetic turf areas, made by an infill of rubber granulates from used tyres or virgin rubber which contain compounds such as PAHs and heavy metals, are widespread in almost all sport facilities.
We collected different samples of rubber granulates from nine synthetic fields where the levels of 16 EPA's priority PAHs have been evaluated by Soxhlet extraction and HPLC analysis.
Then, a sequence of proofs was carried out at 60°C, a temperature that these rubber granulates can easily reach in the environment, to see whether PAHs release occurs and at which concentrations and to estimate the "hazard"by breathing for an athlete who trains on these fields.
The results showed high concentrations of PAHs in all samples of rubber granulates exceeding the threshold values imposed by the "Italian National Amateur League"(LND). The sequence of proof at 60°C, from the same granules, shows that every time this temperature is reached there is a little release of PAH compounds that does not decrease over time, suggesting a chronic contamination related to these areas. Through the airways, after attendance at these surfaces, it was estimated that an athlete who weights 70kg inhales from 0.02 to 0.149 µg/kg body weight (b.w.) of BaPeq per day, an amount considerably higher than the virtually safe dose.
The main conclusion we can draw from this preliminary study, which will be validated by further investigations both in field and in laboratory, is that synthetic fields release PAHs at any rise in temperature of the surface and this does not make them completely safe for public health. In fact, theoretical estimates made by extrapolating data obtained in the laboratory showed that the toxicity equivalent (TEQ) of the evaporated of the different granules is hardly negligible and weighs deeply on the total load of PAHs a man takes daily via different routes.

**Intense sweeteners in the environment- is there a reason for concern for wildlife effects?**

AD Lillicrap[1], K Langford[1], D Huggett[2], KE Tollefsen[1]
[1]NIVA, OSLO, Norway
[2]University of North Texas, TEXAS, United States of America

Intense sweeteners such as aspartame, acesulfame K, saccharin and sucralose are produced and used in large quantities in all major markets of the world as low calorie sugar substitutes. Many of these sweeteners pass through the body either unaltered or as modified compounds and are ultimately released to the environment predominantly through the sewage system. Some of these sweeteners have been detected in various environmental compartments and has raised concern about potential biological effects in non-target species living in areas receiving discharges from anthropological activities. Existing data on fate and effects of intense sweeteners in the environment and novel experimental data for the accumulation and genomic (transcriptional) effects of the intense sweetener sucralose will be presented to elucidate whether these compounds may cause adverse effects to aquatic animals such as plants, algae, crustaceans and fish. The bioaccumulation studies, which were performed with the algae Pseudokirchneriella subcapitata, the crustacean Daphnia magna and zebrafish (Danio rerio), were all conducted as semi-static exposure studies over a period of 48 hours with two concentrations of sucralose (10 and 100 mg/L), with analytical determination of sucralose in both water and biota. Chronic toxicity tests show that sucralsoe at concentrations of 1-100 mg/L did not adversely affect the growth of neither the aquatic plant Lemna gibba nor the survival, growth or reproduction of the mysid shrimp Americamysis bahia. Additionally, the hepatic transcriptional response in Zebrafish (Danio rerio) after 48h waterborne exposure to 1-100 mg/L sucralose was determined by microarray-assisted analysis as a pre-screening tool for identifying potential biological effects of the compound in non-target organisms. A combination of data from literature and the experimental approaches will be used to assess the risk posed by sucralose and other intense sweeteners to aquatic organism under relevant exposure scenarios.

**Alkylphenols and Alkylphenol ethoxylates in consumer goods and their contribution to a Wastewater Treatment Plant in Stockholm, Sweden**

LC Sörme[1], N Månsson[2], C Wahlberg[3], B Bergbäck[2]
[1]Statistics Sweden, STOCKHOLM, Sweden
[2]Linnaeus University, KALMAR, Sweden
[3]Stockholm Water Co, STOCKHOLM, Sweden

Stockholm has been a case study in several Substance Flow Analyses (SFA:s) published. There is a research tradition in the Stockholm studies with a lot of empiric data of the content in goods and emission factors to be able to estimate the inflow, stock and emissions of the substances. The SFA research started with heavy metals and has been followed by organic substances. Knowledge of the sources is necessary for the waste water treatment works to be able to mitigate pollutants before they reach the sewers.
Alkylphenols and alkylphenol ethoxylates are widely used in various applications that are partly under environmental restrictions within Europe. The study set out to analyze the most important sources of this large group of organic compounds in an urban wastewater system using SFA methodology. The study covered the technosphere in Stockholm, Sweden allowing a comparison of 13 groups of goods' emissions to wastewater. The groups were: textile and leather, cleaning products (e.g. cleaning agents for households and industry, washing powder), personal care products, paint and lacquers, engineering industry (degreasing products, lubricants), glue, concrete, plastics, agriculture products, laboratory chemicals, photographic chemicals, paper and others. Several different data sources were used; national authorities (Statistics Sweden and Swedish Chemical Agency), trade associations, businesses and non-governmental organizations (NGOs). Earlier measurements of the content of alkylphenols and alkylphenolethoxylates in textiles were the most important data sources to the contribution from textiles. The main body of data was taken from the Product Register at the Swedish Chemical Agency. 78 different CAS numbers for alkylphenols and alkylphenol ethoxylates were included. It was found that the groups of textiles and cleaning agents were the major sources to wastewater, while the group's personal care products and paint and lacquers give smaller contributions. The content of alkylphenol ethoxylates

in goods, especially in textiles, is a most significant source and is probably valid for other urban areas as well.

**MO 128**

**Leaching of halogen free flame retardants (HFFRs) from polymers**

SH Brandsma[1], J de Boer[1], P Krystek[2], P Clarke[3], P Cusack[3], PEG Leonards[1]
[1]Institute for Environmental Studies (IVM), AMSTERDAM, The Netherlands
[2]MiPlaza, Philips Research Europe, EINDHOVEN, The Netherlands
[3]ITRI, ST. ALBANS, United Kingdom

Information about the production, distribution and consumption of flame retardants in electric and electronics (E&E) equipment (plastics) is well described. However, there is a knowledge gap in the amount of flame retardants leaching from plastics of electric and electronic (E&E) equipment to the environment. In the EU funded project ENFIRO halogen free flame retardants (HFFR) are studied that are viable alternatives to specific commercial brominated flame retardant (BFR). Leaching experiments on BFRs from different types of plastics has been described in literature, however, limited information on leaching of HFFRs is available. Six of the fifteen selected HFFRs that are studied in ENFIRO are metal based flame retardants. Metal based flame retardants are stable in the plastic (polymer) product, but are dissociate in the environment. Monitoring of the fate of metal-based HFFRs in the environment is therefore difficult. Therefore, leaching experiments of HFFRs from plastics is an alternative method that may contribute to the exposure and risks assessment and understanding of the fate of HFFRs in the environment. The current study shows the leaching properties of different HFFRs from polymers in comparison with BFRs. Thereby, the influences of pellets vs. moulded plates and pH on the leaching properties are taken into account. Two types of leaching protocols were tested. The first is the TLCP protocol from the US EPA that use worse-case leaching conditions (low pH) to simulate a municipal waste landfill, to study if waste has a characteristic toxicity and therefore is hazardous. The second protocol is DIN 38414-S4 that determines the leaching by water, and has been widely used for regulatory purposes in Europe. The results show that no differences in leaching properties between the DIN and TCLP methods for two metal-based PBT pellets were found. Higher rate coefficients of HFFRs leaching from PBT pellets than from PBT moulded plates were found, which is probably a results of the differences in surface:volume ratio. Important aspects for further study are the influence of steady state conditions vs. flow through leaching systems, and the influence of leaching conditions (e.g. salinity, humic acids) to simulate different environmental conditions.

**MO 130**

**Measurement of release rate of plastic additives from consumer products using Micro chamber method**

KT Tsunemi, AK Kawamoto
National Institute of Advanced Industrial Science and Technology, TSUKUBA, Japan

To determine the release rate of SVOC during service life of products, we measured emission rate of plasticizers from PVC products and flame retardants from home appliances by a microchamber method newly developed for SVOC. The microchamber method which has two processes of emission test and thermal desorption test, was elaborated in Japan and published in the JIS A 1904 "Determination of the emission of semi volatile organic compounds for building products -- Micro chamber method"in 2008. In Europe, there is no acceptable method for measuring SVOCs; therefore, the JIS A 1904 is considered to be incorporated as ISO regulations.
First, we not only used product samples received from industrial companies, but also prepared pressed plastic sheets containing plasticizers and flame retardants for standard test samples. Second, release tests were conducted focusing on parameters of thickness of sheets, concentration of chemicals and temperature, input flow rate and duration of emission test. Then, we analyzed and quantified the release rate of DEHP, DINP, DIDP, decaBDE, TPP, BDP and antimony trioxide from the samples of products and sheets.
As a result, the release rate of plasticizers was limitedly influenced by the thickness of sheets, concentration of chemicals and input flow rate, while the release rate became increased at a higher temperature due to an increase in a vapor pressure of the compound. The release rates of flame retardants except TPP fell below the lower limit of detection in all samples at high temperature at 60°C and duration of two weeks. Based on these results, we examined several procedures to estimate the release rate of plastic additives from consumer products.

**MO 131**

**Missing links in the regulatory chain controlling emissions of hazardous chemicals from articles**

L Molander[1], M Breitholtz[2], C Rudén[1]
[1]Royal Institute of Technology, STOCKHOLM, Sweden
[2]Stockholm University, STOCKHOLM, Sweden

It is widely acknowledged that the management of risks associated with chemicals in articles, including consumer products, need to be improved. From a chemical and ecotoxicological point of view, it is crucial that the articles' whole life cycle is taken into account in this effort, i.e. design and manufacturing, use, and end-of-life including the waste phase.
The purpose of the present study is to empirically analyze to what extent European legislations that include measures to control emissions of chemicals from articles throughout their life cycle are coherent or not. To illustrate this, the regulation of a number of case-study chemicals, used in various consumer products and in high volumes, is scrutinized.
This analysis identifies missing regulatory links between the rules that are relevant for the manufacturing and use phases and the rules applicable to the end-of-life phase. Many consumer products, such as clothes and furniture, are only regulated by REACH and REACH regulates the use of chemicals in articles only to a very limited extent. Product-specific directives, such as the Toys Safety Directive and the RoHS Directive, are therefore important complements in controlling the use of hazardous chemicals in articles. However, with the exception of the RoHS (and WEEE) directives, a clear connection to the rules for waste is missing in the regulatory system. Clear links are also missing between the rules regulating chemical emissions during the articles' life cycle and the maximum environmental concentration limits, set for e.g. sludge and surface water. These legislative gaps will encourage end-of-pipe solutions, rather than actions to manage the source of the problem.
The Waste Directive, the Water Framework Directive and the Sludge Directive all refer to EU environmental and waste policies. These policies are based on the precautionary principle, and state that preventive action should be taken, that environmental damage should be rectified at source and that the polluter should pay. The lack of connection between the rules regulating different phases of an article's life cycle makes these objectives difficult to fulfill. We argue that to obtain a sustainable development it is necessary to minimize the input of hazardous chemicals into articles, so that waste and other end-products, such as ash materials and sludge, can be recovered and used without harming human health or the environment.

**MO 132**

**Source classification framework for an optimized European wide emission control strategy**

HC Holten Lützhøft[1], E Donner[2], A Ledin[3], E Eriksson[1]
[1]Technical University of Denmark, KGS. LYNGBY, Denmark
[2]University of South Australia, MAWSON LAKES, Australia
[3]Lund University, LUND, Sweden

European legislation such as the Water Framework Directive (WFD) from 2000 and the Environmental Quality Standards Directive and the Marine Strategy Framework Directive both from 2008 focus on a range of priority substances (PSs) with the aim of obtaining an ecological and chemical healthy environment. This should be obtained through reducing releases or phasing out of discharges said chemicals. In order to appropriately design emission control strategies (ECSs) and monitor releases before and after implementation of various measures it is required to identify pollution sources and releases, and thereby establish an appropriate inventory containing such information. Suited for this purpose a Source Classification Framework (SCF) was developed. It consists of harmonized European classification codes for economic activities and emission processes combined with the CAS# for the PS as well as an urban structure descriptor. It also includes a release profile descriptor and when ever possible the release factor describing the extent of PS release from a given pollution source, i.e. commodity or activity. It has been possible to establish PS emission inventories for a given catchment of an urban environment by testing the approach on a range of the PSs listed on the WFD, and thereby identify potential problematic pollution sources. To the extent published data on release factors allows it, it has also been possible to quantify PS load to the considered catchment and thereby compare with European environmental quality standards for the considered PSs. The developed SCF emphasized the need for further knowledge and research within the area of quantification of PS releases from given commodities and activities. These release factors are required for a more thorough, solid and valid quantification of the PS environmental emission. The SCF also provides a well structured approach for European pollutant source and release classification and management. With further European wide implementation, the SCF has the potential for an optimized ECS in order to obtain good chemical status of European water bodies.

**MO 133**

**Emissions of chemicals from the economy-wide stock of plastic material - a first model iteration for Sweden**

JK Westerdahl[1], T Rydberg[1], S Molander[2], J Tivander[2], F Fuhrman[2], PL Andersson[3], P Haglund[3], T Holmgren[3]
[1]IVL Swedish Environmental Research Institute, GOTHENBURG, Sweden
[2]Chalmers University of Technology, GOTHENBURG, Sweden
[3]Umeå University, UMEÅ, Sweden

Estimating the size of the problem with release, fate, exposure and effects from the human use of chemical substances of materials and consumer products is daunting. More than 100,000 chemical substances are in commercial use and a reasonable description of their existence in, and release from, plastic polymers, glues, paints, fibres, lubricants etc. comprise a big challenge. In this study, a generic emission model has been developed and applied to estimate emissions of a set of organic chemicals from products. The scope of the estimate is emissions from products containing plastic materials during their average lifetime within the geographical boundaries of Sweden. The customs Combined Nomenclature has been used to divide the products into categories for which the chemical composition, surface area, thickness and accumulated stock in society has been described and estimated using several approaches for approximation in cases where data have been lacking. For this, information from national trade statistics as well as lifecycle assessments and building product declarations was used. Anti-oxidants, flame retardants and plasticisers are among the most interesting use categories of additives that are emitted in significant quantities. Thus for anti-oxidants in plastic material in the economy-wide product stock in Sweden as an example, the emissions in the service-life were estimated to be almost 500 tons/year divided on 32 individual chemical organic substances, stemming from a stock of anti-oxidants of 84000 tons, contained in a stock of plastic material of 24 million tons.
Until now, the method has only been used to estimate emissions of additives from plastic materials, but it is believed to also be applicable to other materials. However, the uncertainties in the estimations are currently large, which is partly due to model uncertainties but to a large extent also due to uncertainties in the input data.

**MO 134**

**From product flow data to organic substance emissions to the environment - the case of PVC flooring**

F Fuhrman[1], S Molander[1], J Tivander[1], L Sörme[2], H Brolinson[2], T Holmgren[3], P Haglund[3], P Andersson[3]
[1]Chalmers University of Technology, GOTHENBURG, Sweden
[2]Statistics Sweden, STOCKHOLM, Sweden
[3]Umeå University, UMEÅ, Sweden

This case study on PVC flooring investigates the possibilities and barriers to extract and combine Swedish product flow data from Statistics Sweden, in order to derive data detailed enough to populate a developed emission model and execute calculations on total emissions from all PVC flooring in Sweden during one year. A comparison is made, between calculated emissions using either product flow data from Statistics Sweden or from other domestic floor branch sources.
At Statistics Sweden, existing databases, published statistics and available methods were used for identifying and illustrating the possible methods and barriers for extraction and combination of product flow data. For calculations of emissions a combined material flow and diffusive mass transfer model was developed and used.
This case study shows that the data categories and the methods needed for estimating the accumulated product area exist at Statistics Sweden, in principle, but the data is sometimes too aggregated or too protected to make the calculations on a detailed product category level, as in this case for PVC flooring. Using product flow data from the least aggregated level of the Combined Nomenclature, for PVC flooring, generates calculated emissions three times higher than the emissions calculated from the more specific product flow data from The Swedish Flooring Trade Association.
The PVC flooring case study boils down to the facing of a trade off when it comes to national emission assessment of several product categories; using data from Statistics Sweden generates emissions within a reasonable period of time, but with aggregated and in this case, too high values - using branch product flow data generates more accurate emission values but is not a plausible option due to the steep increase in resource demands.

**Evaluation of the effects of titanium silicate nanoparticles in tadpoles of Pelophylax perezi (Seoane, 1885)**

PN Salvaterra[1], R Pereira[2], I Domingues[2], MG Alves[3], RA Carvalho[4], AMM Soares[2], I Lopes[2]
[1]CESAM, AVEIRO, Portugal
[2]CESAM & Dept. Biology-Univ. Aveiro, AVEIRO, Portugal
[3]Universidade da beira Interior, COVILHÃ, Portugal
[4]Universidade de Coimbra, COIMBRA, Portugal

Due to the growing production and usage of titanium silicate nanoparticles (NP-TiSiO4) in a wide range of products and industrial applications, it is expected soon to be found in the environment. Since these NP tend to form large aggregates when suspended in aqueous media, it is presumed that, when entering in the aquatic environment, they will settle over the sediment. Therefore, benthic species, or organisms that actively interact with the sediment will constitute key receptors of these NP. Accordingly, this work intended to evaluate the effects of NP-TiSiO4 in tadpoles of the frog species Pelophylax perezi (Seoane, 1885), as this life stage uses and compete for sediment as a nutritional resource. To attain this objective, tadpoles at Gosner stage 24-25 were exposed, for 96-h, to a series of five concentrations of the NP-TiSiO4. At the end of the assay, mortality, behavioral shifts, and enzymatic activity of acetyl-cholinesterase (Ache), glutathione S-transferase (GST), lactate dehydrogenase (LDH) and catalase (CAT), were monitored. Mortality never exceeded 20% for the control and for all tested concentrations of NP-TiSiO4. Significant behavioral changes were also not observed. However, the analysis of enzymatic activities revealed a significant activation of CAT and LDH when exposed to the lowest concentration. No significant changes were observed for Ache or GST. Proton nuclear magnetic resonance (1H-NMR) analysis for lactate, glucose and alanine content in NP-TiSiO4 exposed tadpoles will be presented.

**MO 139**

**Salinity and copper interactive effects on tadpoles of the green frog Pelophylax perezi (Seoane, 1885)**

BRF Santos[1], R Ribeiro[2], R Pereira[3], I Domingues[3], AMVM Soares[3], I Lopes[3]
[1]University of Aveiro, AVEIRO, Portugal
[2]IMAR - Instituto do Mar, Departamento de Zoologia, Universidade de Coimbra, COIMBRA, Portugal
[3]CESAM & Departamento de Biologia, Universidade de Aveiro, AVEIRO, Portugal

Several works have been focused on metal contamination of freshwater ecosystems and its impact on amphibians. It is expected that in the future, such metal impacted populations of amphibians will have to deal with additional stressors associated with global climate changes, namely increased salinity due to sea level rise. Accordingly, this study intended to assess the interactive effects of salinity and the metal copper on tadpoles of the green frog Pelophylax perezi (Seoane, 1885). To attain this objective, single and combined effects of salinity and copper on survival of larval stages of P. perezi were evaluated in a multifactorial design and enzymatic activities were quantified. Larval stages of the P. perezi were collected in the field and kept in the laboratory for at least 24h in the artificial medium FETAX. Tadpoles (Gosner stage 25-28) were exposed to a gradient of concentrations of Cu2+ (0 to 2.4 mg/l), NaCl (0 to 2 mg/l) and both. Increasing copper concentrations caused an increase in the activity of ChE and catalase, and a decrease in the activity of LDH and GST. When combined with intermediate concentrations of NaCl these trends were attenuated. Results of mortality showed effects at none salinity level. Concentrations of copper above 0.8 mg/l revealed a high mortality rate. Copper combined with intermediate concentrations of NaCl were less lethal than the metal ion alone, indicating the occurrence of antagonistic effects. Biochemical analysis support these results. It is therefore suggested that a moderated increase in salinity would have a shield effect against copper toxicity for tadpoles.

**Metals of priority concern in early life stages of reptiles: maternal transfer and bioaccumulation**

BBA Grillitsch[1], LC Schiesari[2], H Grillitsch[3]
[1]University of Veterinary Medicine of Vienna, VIENNA, Austria
[2]University of Sao Paulo, Brazil, SAO PAULO, Brazil
[3]Natural History Museum of Vienna, VIENNA, Austria

Environmental contamination with metals is a serious problem worldwide. Cadmium, lead and mercury rank highest among the pollutants of regulatory concern, are known to bioaccumulate, cause adverse effects of priority concern such as carcinogenicity, neurotoxicity, reproductive and developmental toxicity, and are Suspected Endocrine Disrupters. Over one in five reptile species are threatened with extinction both worldwide and at the EU level, and pollution represents a main category of threat. Among the almost 300 publications on the ecotoxicity of metals in reptiles reviewed [1], overall 46 publications reported concentrations of 21 metals in 18 different "transgenerational compartments"for 30 reptile species with focus put on Cd, Hg, and Pb (43 publications) for 23 species with half of them falling into the Lower Risk IUCN threat status category. Information is available for only four out of 151 European reptile species. The present review confirmed that early life stages of reptiles are almost ubiquitously exposed to the metals Cd, Hg, and Pb which were detected in male and female gonadal systems during gametogenesis, fertilization, and egg shell formation, as well as in laid eggs, embryos and hatchlings; were detected in the vast majority of the samples analysed; and were transferred via both maternal tissues and external incubation substrates to the progeny where they accumulated in a dose-dependent manner. Moreover, mean concentration levels of these metals detected in the early developmental stages of reptiles matched those reported for mammals and birds, and fell within the range of reproductive and developmental toxicity thresholds reported for these taxa. However, for Cd, Hg, and Pb in reptiles, no critical metal concentrations in reproductive tissues, and no exposure-effect relationships could be established. Based on the published data set, the threat metals of priority concern might pose upon threatened reptile species can not been assessed. [1] Grillitsch B.; Schiesari L. 2010. The ecotoxicology of metals in reptiles. p. 337-448. Appendix: Metal contamination in reptiles. p. 553-903. In: Sparling DW; Linder G; Bishop CA; Krest S. (Editors). Ecotoxicology of amphibians and reptiles. SETAC, CRC Press, Boca Raton. 916 p.

## ET10 - Linking chemical residues with biological responses in wildlife

**MO 146**

**Predicting exposure of bats to soil-associated heavy metals**

BV Hernout[1], KE Somerwill[2], K Arnold[1], C Mcclean[1], G Grimm[3], ABA Boxall[1]
[1]University of York, YORK, United Kingdom
[2]FERA, YORK, United Kingdom
[3]Helmholtz Center for Environmental Research, LEIPZIG, Germany

Wildlife may be exposed to heavy metals in soils via uptake through the food chain. The accumulated metals may then affect the health of the wildlife species. It is therefore important to develop a better understanding of the potential for wildlife to be exposed to metals via the food change and to assess the subsequent risks. In this study, we developed a spatial model to predict the exposure of insectivorous bats to cadmium, lead, copper and zinc in soils. Data were collected on the distribution of 14 bat species in the UK, the diet of bat species, bioaccumulation factors for invertebrate prey and concentrations of heavy metals in soils across England and Wales. These data were used in a GIS-based exposure model to estimate daily levels of exposure for heavy metals in bats across England and Wales. Our results show that highest exposure occurs around industrial areas, where predicted exposures for several bat species are at a level at which toxicological effects might be expected. As many species of European bats are of conservation concern, this model has the potential to identify populations that might be particularly vulnerable to environmental contaminants. Further work is planned to evaluate the model against experimental monitoring data of bats and to explore in more detail the transfer of metals through different stages of the food chain.

**MO 147**

**Use of MDA as biomarker of lipid peroxidation in roe deer (Capreolus capreolus): the influence of gender**

M Pérez-López[1], D Hernández Moreno[1], MP Míguez Santiyán[1], A López Beceiro[2], LE Fidalgo[2], L Rigueira[2], F Soler Rodríguez[1], I de la Casa Resino[1]
[1]Toxicology Unit. Fac of Veterinary Medicine (UEX), CACERES, Spain
[2]Fac of Veterinary Medicine. University of Santiago de Compostela, LUGO, Spain

Oxygen metabolism in aerobic organisms implies the formation of reactive oxygen species (ROS), their production being greatly enhanced by exogenous factors like environment pollutants, drugs, radiation and pathogens. These ROS can oxidize biologically relevant molecules leading to alterations in normal cell and tissue functions, but this oxidation is functionally minimized by a broad spectrum of antioxidant defenses (AD). Therefore, a steady-state rate of ROS production, molecule oxidation, and antioxidant consumption is continuously taking place in aerobic cells and tissues. One of the most studied processes in relation to damage produced by ROS is the lipid peroxidation. Lipid peroxidation is a complex process, which can be considered as a sequence of events initiated by a hydrogen atom abstraction, followed by reaction of oxygen with the subsequently formed radical, and by further free radical chain reactions. Lipid peroxidation is an important process initiated by free radicals, which is involved in the events leading to cell death. In the present study the thio-barbituric assay for malondialdehyde (MDA), biomarker of both primary and secondary decomposition of lipid peroxidation products, was used as indirect measure of endogenous lipid peroxidation in three different organs (liver, kidney and lung) of male and female roe deer (*Capreolus capreolus*) from NW Spain, in order to assess the influence of this variable (gender) in future biomonitoring studies in the wild. The results showed higher MDA levels in male than in female liver ($0.292 \pm 0.045$ and $0.160 \pm 0.023$ nmol/mg protein, respectively), this difference being statistically significant ($p< 0.05$). This result could be explained according to the fact that in females, the hormone estradiol, like other protective molecules, may act by regenerating endogenous antioxidants present in membranes, thus delaying the appearance of lipid peroxides, like MDA. With respect to the other tissues, kidney and lung samples showed quite similar levels of MDA in both males and females ($0.212 \pm 0.020$ and $0.213 \pm 0.020$ nmol/mg protein respectively), with no statistical relevance.
The findings are indicative that gender can play an important role in the expression of oxidative stress in the case of hepatic tissue, rendering this variable of interest in biomonitoring programs.

**MO 148**

**Incidence of intersex and reproductive status in the clam Scrobicularia plana from 13 sites in NW France**

O Fossi Tankoua[1], F Perisi[1], C Amiard-Triquet[1], B Berthet[1], S Aït-Aïssa[2], K Lemenach[3], H Budzinski[3]
[1]Université de Nantes, NANTES, France
[2]INERIS, VERNEUIL EN HALATTE, France
[3]LPTC, Université Bordeaux, BORDEAUX, France

The endobenthic clam *Scrobicularia plana* is important for the structure and functioning of estuarine and coastal mudflats, and thus the reproduction success of this species is a topic of interest for environmental conservation. In thirteen estuaries from NW France differing by their degree of contamination (as documented by the data of RNO for Réseau National d'Observation, now ROCCH, Réseau d'Observation de la Contamination Chimique du milieu marin at http://wwz.ifremer.fr/envlit/), intersex and different parameters linked to reproduction (sex-ratio, gonadosomatic index) were examined in *S. plana* collected at the beginning of gametogenesis and at the peak of sexual maturity. Both temporal and intersite differences were shown. Some reports exists showing that the presence of several endocrine disrupting chemicals (EDCs) may be directly linked to the incidence of intersex in *S. plana* and, in other bivalve species, an induction of female-biased sex ratios were observed after exposure to EDCs at the larval stage. Thus, the presence of EDCs in superficial sediments collected in parallel to clams was investigated by using an approach combining quantitative chemical analyses of the main classes of EDCs and a battery of *in vitro* bioassays allowing the quantification of receptor-mediated activities, namely estrogen (ER), androgen (AR) and dioxin (AhR) receptors. In addition, the reproductive success may be impaired indirectly when species used as food are impacted in contaminated sites, limiting food availability and then energy ressources devoted to the reproduction of consumers. This hypothesis was tested concurrently with endocrine disruption by determining hepatosomatic indices and measuring chlorophyll and phaeopigments in superficial sediments, the microphytobenthos of which is a major food source for deposit-feeding bivalves such as *S. plana*.

**Cellular energy allocation and biomarkers of oxidative stress in the green crab (Carcinus maenas) after exposure to a polycyclic aromatic hydrocarbon (fluoranthene)**

AP Rodrigues[1], K Lehtonen[2], L Guilhermino[1], L Guimarães[3]
[1]ICBAS, CIIMAR, PORTO, Portugal
[2]Finnish Environment Institute, HELSINKI, Finland
[3]ICBAS, PORTO, Portugal

Fluoranthene (FLU) is a priority polycyclic aromatic hydrocarbon that has been detected in aquatic systems around the world, including in sediments from Northern Portuguese estuaries. Several works have shown its ability to induce adverse effects in wild aquatic species. *Carcinus* *maenas* is a key inhabitant of European estuarine and coastal systems for which exposure to pollutants has been shown to alter physiological and biochemical responses. Despite this, information on sublethal effects of FLU in *C. maenas* is scarce or unavailable, particularly regarding physiological parameters related to the maintenance and performance of the organisms such as net energy balance and oxidative stress. To assess the effects of FLU exposure in relation to tissue residues accumulation, a 7-day laboratory exposure to concentrations ranging from 2.56 to 100 μg/L was performed. Crabs were caught in a reference estuary, acclimated in filtered seawater (salinity 15"ð, temperature 16±1°C, photoperiod 16hL:8hD), and individually exposed to FLU. At the end of the bioassay the crabs were ice-anaesthetised and samples of tissues were collected for chemical analysis and biochemical determinations, namely: the activity of the enzymes lactate dehydrogenase (LDH), isocitrate dehydrogenase (IDH), gluthatione-S-transferases (GST), gluthatione peroxidase (GPx), gluthatione reductase (GR), the levels of total gluthationes (GT) and lipid peroxidation (LPO), the content in glycogen, lipids and proteins and the mitochondrial electron transport activity (ETS). Despite low tissue accumulation, significant alterations of several biomarkers were detected. An induction of GST activity was found in the animals exposed to the 3 highest test concentrations. A decreasing trend in LPO levels was also found, with significant differences detected in crabs exposed to 100 μg/L. Available energy reserves were significantly higher in the hepatopancreas than in the muscle. Moreover, the latter were significantly decreased in crabs exposed to FLU. Overall, FLU enhanced C. maenas biotransformation processes (GST activity) and altered muscle energy availability.

This work was supported by nacional (MCTES, Foundation for Science and Technology) and European funds (FEDER) through CRABTHEMES Project (FCOMP-01-0124-FEDER-007383, FCOMPETE Program) and a PhD grant to A. Rodrigues (SFRH/BD/65456/2009).

### MO 150

**Is the reproduction of Donax trunculus affected by their site of origin contrasted by their level of contamination?**

S Tlili[1], I Métais[1], H Boussetta[2], C Mouneyrac[1]
[1]University of Nantes, NANTES, France
[2]University of Sousse, SOUSSE, Tunisia

Coastal zones are extremely fragile due to increasing stress from anthropogenic activities (urbanization, intensive agriculture[3DOTS]). Thereby, mixtures of contaminants are present in these zones.

Since mollusk bivalves are good bioindicators of environmental quality, we used the suspension-feeder bivalve Donax trunculus, largely distributed in West-African, European and Mediterranean coasts. The reproductive cycle of bivalves is regulated by several natural environmental factors but exposure to chemical pollutants can also interfere and may result in advanced or delayed spawning season.

To our knowledge, the gametogenic cycle of D. trunculus has not yet been used as biomonitoring tool in ecotoxicological surveys. The aim of this study was to examine over a year physiological reproductive endpoints (sex-ratio, gametogenic and energy reserve cycles) in D. trunculus originating from two sites differing by their level of contamination. Specimens were collected bimonthly from November 2008 to October 2009 from a polluted site (Radès Méliane) and a comparatively reference site (Sidi Jehmi) in the Gulf of Tunis (Tunisia). Five stages were depicted by histological examination of gonads: indifferentiated, development, mature, spawn and spent. Differences in the gametogenic cycle according to the site of origin of bivalves were observed. The spawning period began in March and was maximum in May in bivalves from both sites, but the percentage of spawning animals was higher in the polluted site (March: 30 %, May: 89.47 %) vs reference site (March: 8.57%, May: 71.42 %). The spawning period was shorter (beginning: March, end: May) in animals from the polluted site comparatively to the reference site (beginning: March, end: October). The sex-ratio was equilibrated in bivalves from both sites excepted in March in the polluted site where the percentage of females (66.6%) was higher than males (33.3%). Energy reserves (Glycogen, lipids) were higher in March and May comparatively to the other periods in bivalves from both sites. Lower energy reserves levels in animals from the polluted site could be explained by the cost of tolerance of bivalves exposed during long time to sublethal levels of contaminants. Indeed, increased defense and damage biomarkers were depicted in animals from the polluted site (Tlili et al., 2010). Therefore, D. trunculus appears as a suitable sentinel species for the assessment of the ecotoxicological risk of contaminants such as endocrine disruptors.

### MO 151

**Use of biomarkers in Cyprinus carpio as tools in biomonitoring programs: experimental exposition to the pesticide Deltamethrin**

C Ensibi[1], MN Daly Yahya[1], D Hernández Moreno[2], MP Míguez Santiyán[2], F Soler Rodríguez[2], M Pérez-López[2]
[1]University 7 novembre Carthage, ZARZOUNA, Tunisia
[2]Toxicology Unit. Fac of Veterinary Medicine (UEX), CACERES, Spain

The presence of toxic pollutants in aquatic ecosystems possesses a serious threat to environmental health. Use of biomarkers in fish is considered as a cost effective strategy to obtain information on the state of the aquatic environment and the effect of pollutants on living resources. Biomarkers are defined as changes in biological responses (ranging from molecular through cellular and physiological responses to behavioral responses) which can be related to exposure or to toxic effects of environmental chemicals. With these considerations, the objective of this study was to evaluate the usefulness of a suite of both enzymatic and non-enzymatic biomarkers in *Cyprinus carpio* L. in assessing and monitoring pollution of aquatic environments.

For this purpose, fish were exposed for 30 days to deltamethrin, which was added to the tank water at concentrations of 0, 0.08, 0.4 and 0.8 μg/L. Animals from every tank were sampled at the beginning and at 4, 15 and 30 days of the experience, and their liver and brain were isolated. Subcellular fractions were prepared by differential centrifugation in an appropriate buffer. Ethoxyresorufin-o-deethylase (EROD) and glutathione S-transferase (GST) were the activities measured in liver tissue, whereas Acetylcholinesterase (AChE) activity was measured in brain tissue. Moreover, the effect of pesticide on lipid peroxidation was evaluated, by measuring hepatic malondialdehyde (MDA).

A significant increase of LPO was observed after 15 and 30 day of exposure to the concentration 0.8 μg/L when compared to control group. GST activity significantly increased in fish exposed to both concentrations of 0.08 and 0. 8 μg/L of pesticides, but only after 30 days of exposure, when compared to controls. With regards to both acetylcholinesterase (AChE) and EROD activity, no significant changes in enzyme activity were found in any of the experimental groups when compared to the controls.

The results revealed that response of brain AChE, hepatic EROD, GST and LPO of common carp could be used as a suite of biomarkers in future biomonitoring programs in assessing pollution status and pollution trends in water resources.

**Evaluation of the contamination of the Loire estuary by endocrine disruptors**

I Blanchet-Letrouvé[1], OFT Fossi Tankoua[1], LP Poirier[1], SAA Aït-Aissa[2], CH Herrenknecht[1], HB Budzinski[3], SB Baloche[4], SD Dufour[4], CM Mouneyrac[1]
[1]University of Nantes, NANTES CEDEX 1, France
[2]INERIS,, VERNEUIL EN HALATTE, France
[3]3LPTC, Université Bordeaux I, TALENCE, France
[4]4Muséum National d'Histoire Naturelle, DMPA, PARIS, France

Estuaries are ecosystems of high productivity, crucial in the life history of fishes, invertebrates, birds, including commercially important species, but anthropogenic activities such as urban effluents are often the main factors responsible for water quality degradation. Complex mixtures of contaminants are present in these zones and in this context; there is a growing interest in the influence of endocrine disruptor compounds (EDCs) on biota physiology. The Loire estuary runs through important urban sites (Nantes, Saint-Nazaire, etc.) with shipping and industrial activities. Moreover, the Loire basin (117,000 km²) represents more than 1/5 of the French territory and drains a lot of tributaries.

The aim of this research is to evaluate the contamination of the Loire estuary by EDCs. Twelve sites along the Loire estuary (from Saint-Nazaire to Ancenis) were selected because of their typology of contamination (agricultural, urban, and industrial) and of their particular configuration (upstream/downstream of an effluent site close to a wastewater treatment plant). The endocrine activities in sediment were followed using various bio-analytical tools (in vitro tests of hormonal activities on cellular cultures). The presence of PAHs and dioxine-like compounds was estimated using the EROD test. The eel Anguilla anguilla was chosen for her ecological representativeness and economical incidence on fishing activities and was collected on 3 sites along the Loire estuary (upstream, intermediate, and downstream). The in situ effects on fish were evaluated by measuring biological variables at the individual level (size, sex, gonads histology, vitellogenin and aromatase).

### MO 153

**Identifying Pb exposure sources in waterbirds and adverse effects on porphyrin metabolism using non-invasive faecal sampling**

M Martinez-Haro[1], MA Taggart[1], RC Martín-Doimeadiós[2], AJ Green[3], R Mateo[1]
[1]Instituto de Investigación en Recursos Cinegéticos (IREC, UCLM-CSIC-JCCM), CIUDAD REAL, Spain
[2]Faculty of Environmental Sciences (UCLM), TOLEDO, Spain
[3]Estación Biológica de Doñana (EBD, CSIC), SEVILLA, Spain

Waterbird feces (mainly mallard (*Anas platyrhynchos*) and coot (*Fulica atra*)) from four wetlands in Southern Spain were collected in the field or during capture (n = 558 and n = 59, respectively) to study lead (Pb) shot ingestion. Pb and aluminum (Al) concentrations, along with Pb isotope signatures in feces were used to track Pb sources in the birds. The profile and concentrations of porphyrins and biliverdin in feces were then used as biomarkers of adverse effects. Feces with Pb concentrations ≥34 μg/g d.w. showed lower Al levels, together with lower $^{206}Pb/^{207}Pb$ and $^{208}Pb/^{207}Pb$ ratios, and higher $^{208}Pb/^{206}Pb$ ratios than feces with <34 μg/g d.w. Isotope signatures and Pb-Al ratios together indicated that Pb shot ingestion caused all the high Pb levels observed, whereas sediment ingestion was linked to lower Pb levels. Coproporphyrin I and protoporphyrin IX were also higher in feces with ≥34 μg/g d.w., indicating measurable disruption in heme synthesis. Non-invasive feces sampling permits the study of the degree of Pb exposure and adverse effects on waterbirds with low effort and minimal disturbance to birds. It also avoids bias associated with capture or hunting. This is the first study of its kind in ducks and coots.

### MO 154

**Organochlorine pesticides in Razorbill (Alca torda) feathers from Southwestern Mediterranean and their correlations with internal tissues**

S Espín, E Martínez-López, P María-Mojica, AJ García-Fernández
University of Murcia, MURCIA, Spain

The aim of this study was to explore the usefulness of feathers as biomonitoring tool for organochlorine pesticides (OC) in a population of 50 razorbills (Alca torda). It was evaluated the distribution pattern of the compounds and correlations between the concentrations found in feathers and OC levels found in internal tissues (liver, brain, subcutaneous fat and abdominal fat) of the same razorbills. Moreover, additional factors such as age, sex and nutritional conditions of the birds were checked in order to evaluate their influence on the level of pollutants in feathers. Fifteen OC were analyzed in feathers, including α-, β- and δ-HCH, lindane, aldrin, dieldrin, endrin, endosulfan I and II, endosulfan sulfate, p,p'-DDT, DDD, DDE, heptachlor and its epoxide. Mean concentrations obtained in this study were ∑Heptachlor 196.27±174.92 ng/g, ∑Drins 61.14±79.60 ng/g, ∑Endosulfan 114.52±154.44 ng/g, ∑DDT 323.56±372.68 ng/g, ∑HCH 174.99±177.87 ng/g. The higher OC levels found in this study compared with other studies are probably influenced by razorbill diet and migration status. Besides, compound persistence seems to be an influential factor in the capacity of the feather to store and excrete organic compounds. Few significant correlations were found between OC levels in feathers and internal tissues, probably conditioned by the time between the molt and the moment of sample collection. According to the levels found in internal tissues, there is no risk associated to OC concentrations found in feathers in razorbills. Further research is necessary to investigate the correlation between concentrations in feathers, internal tissues, and blood in seabirds. Nevertheless, feathers appear to be a promising tool for OC biomonitoring in seabirds, giving a good estimation of OC levels in a population. Acknowledgements: To MICINN and Fundación Seneca for funding the Projects CGL2004-5959/BOS, CGL-2008-4318/BOS and 08758/PI/08. To Generalitat Valenciana for permission to obtain the samples. Silvia Espín is enjoying a grant from the CEIGRAM.

### MO 155

**Development of an analytical method for extracting organochlorine pesticides from feathers**

S Espín, E Martínez-López, P María-Mojica, AJ García-Fernández
University of Murcia, MURCIA, Spain

Currently, the search for non-invasive techniques in pollutants biomonitoring is an ethical and moral obligation. Keratin tissues, such as hair, have been used for persistent organochlorine pollutants studies accumulation, suggesting that keratin units could be interesting for biomonitoring these contaminants. In this sense, feather is the most important keratin tissue in birds, animals which have played an important role in documenting human-induced environmental pollution.

Although most organochlorine pesticides (OC) have been banned in developed countries, they are still frequently found in tissues or fluids samples from several species, specially in agricultural regions, where these contaminants have been widely used in agricultural practices. The aim of this study is the development of an extraction method for 15 OC in feathers, including α-, β-and δ-HCH, lindane, aldrin, dieldrin, endrin, endosulfan I and II, endosulfan sulfate, p,p'-DDT, DDD, DDE, heptachlor and its epoxide. The large number of OC to identify and polarity variations pose problems in the recovery process. In order to solve these problems, different mixtures of organic solvent were prepared to find out which one was the most appropriate. In this way, four methods of OC extraction in feathers were evaluated, and it was selected the most appropriate method testing for recovery, linearity and precision. To study these parameters, mallard (Anas platyrhynchos) feathers were spiked with three different levels of OC standard solution. Finally, in the most appropriate method selected, extraction was done with hexane:acetone, clean up via Florisil column chromatography and elution with a petroleum ether:diethyl ether mix. This method presented a range of recovery for the 15 compounds studied between 46.13 and 146.05%. The linearity showed a good correlation between OC concentrations and chromatographic peak area for each compound, with regression coefficient values (R) greater than 0.96. The variation coefficients obtained for the repeatability and reproducibility are indicative of good technique precision, with values below 20%. Therefore, the technique developed in this work is acceptable and can be used as a method for the extraction in feathers of 15 organochlorine pesticides widely used in some areas. Acknowledgement: To MICINN and Fundación Seneca for funding the Projects CGL2004-5959/BOS, CGL-2008-4318/BOS and 08758/PI/08. Silvia Espín is enjoying a grant from the CEIGRAM.

**PBDEs and legacy POPs in hawk and falcon species from urban environments in British Columbia, Canada, 1999-2009**

E Elliott[1], LK Wilson[1], KG Drouillard[2]
[1]Environment Canada, DELTA, Canada
[2]University of Windsor, WINDSOR, Canada

Liver tissue from Cooper's Hawks (Accipiter cooperii) and peregrine falcons (Falco peregrinus) found dead, 1999 - 2009, in the urbanized Metro Vancouver area were analyzed and compared to samples from southeast Vancouver Island and the Okanagan Valley regions of British Columbia. Cooper's hawks nest in city parks and along treed streets, while peregrines use high rise buildings, bridges and similar structures. Both species are top predators feeding mainly on birds; populations remain throughout the year in many cities, attracted by pigeons, starlings and common bird-feeder species. Past investigations linked population decline of falcon and accipiter species with exposure to legacy POPs, particularly DDE and dieldrin. Recent studies of salvaged eggs and tissues of carcasses have reported accumulation of toxicologically significant concentrations of both legacy POPs and PBDEs. Carcasses were selected only if body condition was good, and the diagnosis of death was trauma. Hepatic ΣPBDE concentrations in 13 Cooper's hawks from Greater Vancouver ranged widely from 30 to 4820 ng/g ww with a geomean of 450 ng/g ww. Similarly, geomean ΣPCBs were 451 ng/g (range 40.5 to 4280 ng/g), and DDE, 1280 ng/g (range 231 - 10,400 ng/g). By comparison, mean ΣPBDEs in three Cooper's hawk livers from the less urbanized Okanagan Valley were only 17.2 ng/g (range 3.2 -133 ng/g); DDE was higher, 1840 ng/g (range 441 to 3800 ng/g), consistent with heavy past use of DDT in that region. Average values and ranges were similar in peregrine falcon samples. Patterns and trends of the various contaminants will be analyzed and compared to trophic level and carbon source using stable isotopes.

**MO 157**

**Relationship between CALUX bioassay and dioxin-like PCB- TEQs in the eggs of predatory birds from the UK**

GM Pereira[1], LA Walker[1], M Coyle[2], RF Shore[1]
[1]CEH, LANCASTER, United Kingdom
[2]Natural England, PETERBOROUGH, United Kingdom

Accumulation of polychlorinated biphenyls (PCBs) in predatory birds has been extensively characterised but it is less clear as to the importance of co-planer PCB congeners in contributing to the sum TEQ concentrations in birds that are a result from exposure to PCBs, dioxins, furans and other polyhalogenated compounds. We analysed eggs from three different wild bird species: gannet (Morus bassanus), merlin (Falco columbarius) and peregrine falcon (Falco peregrinus) from various locations in the UK. Dioxin-like PCB congeners were identified and quantified by GC-ECD and Toxic Equivalent Concentrations (PCB-TEQs) were calculated based on the sum of the dioxin-like PCBs and appropriate toxic equivalent factors for birds. We also assessed the total exposure to dioxin-like compounds (CALUX-TEQ) using chemical- activated luciferase gene expression (CALUX) bioassay. There was a significant correlation between CALUX- and PCBs-TEQ values for each individual species and when data for all three species were pooled. PCB-TEQ concentrations represented almost 100% of the CALUX-TEQs in gannet and merlin eggs, but only 10% in peregrine eggs. Overall, CALUX-and PCB-TEQs gannet and merlin eggs were significantly higher than in peregrine eggs. Our results suggest that, in the UK, PCBs account for most of the TEQ concentrations detected by the CALUX assay in gannets and merlin eggs. Peregrine falcons accumulate fewer Ah-receptor ligands (including dioxin-like PCB congeners) in their eggs than gannets or merlins and it is compounds other than PCBs that largely contribute to the total toxicity.

**MO 158**

**Risk assessment of organohalogen exposure in a Eurasian eage owl (Bubo bubo) population from Southeastern Spain**

P Gómez-Ramírez[1], E Martínez-López[1], P Maria-Mojica[1], S Espín[1], L Ramón[1], AJ Zweers[2], AJ García-Fernández[1], NW van den Brink[2]
[1]University of Murcia, MURCIA, Spain
[2]Alterra, WAGENINGEN, The Netherlands

Exposure to polybrominated diphenyl ethers (PBDEs), polychlorinated biphenyls (PCBs) and organochlorine insecticides (OCs) are associated with some toxic mechanisms that impair bird reproduction and have led to population declines in several bird species. Despite the ban of most of these highly persistent compounds, current environmental concentrations may still be important and pose potential risks. According to the NRC requirements, the Eurasian Eagle Owl (*Bubo bubo*) could be considered a suitable sentinel species for monitoring organohalogen compounds in Southeastern Spain. Moreover, because this nocturnal raptor is a territorial year-round and long lived species, it could be especially useful to reflect local pollution. Between 2004 and 2009, 58 unhatched eggs were collected from monitored nests. Eggs were analysed for 7 PBDEs, 22 PCBs and 23 OCs using a GC-MS. Eggshell thickness was measured as effect parameter. Although average concentrations of the compounds analysed were below known threshold levels, about 8% of our samples exceeded the NOAEC for ∑DDTs (3.6 µg/g wet weight) and one egg presented total PCB levels above NOAEC (7 µg/g wet weight). In addition, about 36% of the eggs exceeded the Total TEQs NOAEC (135 pg/g wet weight) and levels in 17% of the samples were above the LOAEC for Total TEQs (400 pg/g wet weight). TEQ concentrations were negatively related to the metabolisable fraction of PCBs ($F_{prob}$,<0.001) which is indicative of hepatic enzymes induction in the birds exposed. These females could be suffering Ah-receptor-related toxic effects, some of which have been related to altered bird reproduction. Eggshell thinning caused by pp'-DDE exposure was also evidenced by a significant correlation between log-transformed pp´-DDE concentrations and eggshell thickness (P= -0.469, p<0.001), finding about 18% of eggshell thinning when pp´-DDE levels were above 8 µg/g wet weight. The persistence of this degree of thinning over a period of time has been related to population declines in other raptor species. Acknowledgments: Supported by the Spanish Government (CGL2004-5959/BOS, CGL-2008-4318/BOS), Seneca Foundation (08758/PI/08) and WIMEK. Thanks to Autonomous Community of Murcia Region for permission to sampling. Special thanks to M. León-Ortega, E. Pérez, J.A. Lacalle and J.M. Pérez-García for sampling efforts.

**Blood cholinesterase characterization of Ciconia ciconia and Ardea cinerea: potential bioindicator of contamination in birds**

SA Santos, MS Monteiro, AMVM Soares, S Loureiro
CESAM (Centre for Environmental and Marine Studies), AVEIRO, Portugal

One of the most varied and conspicuous group of vertebrates, birds had adapted themselves to the most severe environmental conditions on earth and are usually exposed to xenobiotics in ecosystems. There are a broad range of pesticides, which are used to control pests and disease vectors over large areas as wetlands and agricultural fields, but commonly known to have toxic effects on non-target wildlife. Among them, there are cholinesterase (ChE) inhibiting compounds such as organophosphate (OP) or carbamate (CB) pesticides and metallic elements, that usually are the cause of death of wildlife animals.

This study aimed to characterize blood's ChE and asses its basal activity on the white stork (Ciconia ciconia) and the grey heron (Ardea cinerea), two wading bird species well-known by their foraging habits in shallow-water habitats and possible targets for OP and CB exposure through ingestion and dermal contact. For this, blood samples of both species were taken from healthy individuals inhabiting the Biological Park of Gaia (Parque Biológico de Gaia), Portugal. For each species the ChE activity was measured with three substrates (acetylcholine iodide, propionylthiocholine iodide and S-butyrylthiocholine iodide) and three ChE inhibitors (BW284C51, eserine hemisulphate and iso-OMPA). Both species showed enzimatic activity for all the substrates used, with higher activities when propionylthiocholine iodide was used. The form(s) of ChE activity present in each species will be discussed integrating substrate preferences with specific inhibitors results. These results are crucial for the use of ChE activity as a contamination bioindicator for birds in agricultural areas and environmental monitoring.

**PFOS, PFOA and PFBS induce embryonal hepatic fatty acid oxidation in chicken eggs**

M Nordén, O Westman, N Venizelos, M Engwall
Örebro University, ÖREBRO, Sweden

In this study a new method for toxicity testing is presented which can be used for studies of the effect of environmental pollutants on fatty acid oxidation in avian models. In the current study the method has been used to study the effects the perfluorinated compounds (PFC) perfluorooctane sulfonate (PFOS), perfluorooctanoic acid (PFOA) and perfluorobutane sulfonate (PFBS) on the developing chicken embryo. PFCs have many industrial and commercial applications such as water and stain resistant fabric treatments, fire-fighting foams and lubricants and can be found on a global scale in water and wildlife samples. Fish eating birds have a high exposure to PFCs and levels of perfluoroctanesulfonate (PFOS) have been found in levels over 1µg/g in guillemot eggs from the Baltic Sea (Holmström, 2005). More research is needed to evaluate the effects of this exposure. Chicken eggs were incubated at 37.5°C and injected with a water solution of PFOS, PFOA or PFBS on day four of incubation. On day ten of incubation chicken embryos were dissected and the livers were incubated in vitro with media containing tritium labelled palmitic acid. The ß-oxidation of palmitic acid was measured by liquid scintillation counting of the media to measure the amount of tritiated water created by the metabolic processes. All of the tested chemicals showed induction of the hepatic fatty acid oxidation. The highest induction was 65% and was seen for PFOS at 0.3µg/g. The mechanisms behind the induction are not known but could be due to the structural similarity between these PFCs and fatty acids or coupled to effects on membrane permeability. The lowest observed effect level (LOEL) was 0.1µg/g PFOS. Several of the doses in this study are below environmental levels found in bird eggs which indicate that effects of this kind could be present in some bird populations. Birds in the wild are not exposed to single PFCs but mixtures of PFCs and other pollutants. It is not known how mixtures of PFCs affect this system.

Holmström KE, Järnberg U, Bignert A (2005) Temporal Trends of PFOS and PFOA in Guillemot Eggs from the Baltic Sea, 1968-2003. Environmental Science & Technology 39:80-84.

**Effects of early exposure to BDE-99 on growth, physiology and reproduction in zebra finches and European starlings**

L Eng[1], TD Williams[1], RJ Letcher[2], JE Elliott[2]
[1]Simon Fraser University, BURNABY, Canada
[2]Environment Canada, OTTAWA, Canada

Polybrominated diphenyl ethers (PBDEs) are a class of brominated flame retardants that have become ubiquitous in the environment, and BDE99 is one of the most abundant congeners. There is evidence that PBDEs have a wide range of toxicological effects in birds, including negative effects on reproduction, changes in growth, and altered physiology. Concentrations and effects of PBDEs have been most commonly examined in avian species that are top predators, whereas passerine birds have been less frequently studied. In birds, early life stages are the most sensitive to environmental conditions, and exposure to contaminants during the nestling period may have critical effects at concentrations much lower than those required to affect adults. These effects of exposure may not be evident until reproductive maturity, necessitating long term studies to assess fitness implications. In this study, our objective was to use an integrated avian laboratory and field model system to examine the potential long-term effects of early exposure to BDE99 in passerines. The zebra finch (*Taeniopygia guttata*) is a useful passerine model to monitor effects of contaminants under controlled laboratory conditions, as they reach sexual maturity within 90 days, and readily breed in captivity. The European starling (*Sturnus vulgaris*) can be used as an ecological equivalent for comparative in situ investigations. Starlings are widespread, readily use nest boxes, feed on terrestrial invertebrates, and are easy to sample. In both species, we exposed young for the duration of the nesting cycle to environmentally relevant, sublethal levels of BDE99 (0-250 ng/g bw/day). A preliminary study dosing zebra finch chicks with BDE99 for 21-days during the nestling phase showed that there was a strong dose-dependent relationship for plasma BDE99 levels at 30 days of age. Following dosing, we raised young to sexual maturity. In the zebra finches we monitored female reproductive success, and in the starlings we monitored reproductive development and gonadal growth. For both species we monitored growth, and took blood samples to assess thyroid hormone homeostasis, oxidative stress, immune function, and hematocrit for each treatment group. At our dose levels, few effects on reproduction, growth and physiology were observed.

**MO 162**

**The effect of migration and fasting on fatty acid profiles and organochlorine contaminant burdens in humpback whales**

CA Waugh[1], SM Bengtson Nash[1], P Nicols[2], M Schlabach[3], M Noad[1]
[1]The University of Queensland, GOLD COAST, Australia
[2]CSIRO, HOBART, Australia
[3]NILU, KJELLER, Norway

Humpback whales inhabiting the Southern Ocean are exposed to an as yet uncharacterized level of environmental pollutants, and though not currently considered an at risk species the extreme life history parameters of fasting and migration that characterize this group of mysticetes emphasizes the imminent necessity for toxicokinetic and toxicodynamic analysis. These aforementioned parameters cause the whales fat supplies or blubber to be metabolized and this theoretically forces the release and redistribution of stored toxins such as Persistent Organic Pollutants (POPs), which may result in high circulating levels and adverse health affects. This study focuses specifically on the first generation, or legacy, POPs which encompass the major group of halogenated hydrocarbons, the organochlorines (OCs).

Here we utilize non-destructive skin and blubber samples from free-swimming populations of Southern Ocean humpback whales during two time points of the migration for the purpose of quantifying migration associated OC concentration effects.

**MO 163**

**The toxicological effect of inhalation exposure to nitrocellulose paint thinner fumes (ABRO®, FIAB® and SPRINT®) on selected biochemical and haematological parameters in Wistar albino rats.**

C Patrick-Iwuanyanwu, A Okon, W Areh, B Owubokiri
University of Port Harcourt, PORT HARCOURT, Nigeria

The toxicity effects of the inhalation exposure to fumes of three different brands of nitrocellulose paint thinner (ABRO® , FIAB® and SPRINT®) in wistar albino rats were investigated after 28 days of 4 h daily inhalation exposure. Serum L-alanine aminotransferase (L-ALT), L-aspartate aminotransferase (L-AST) and alkaline phosphatase (ALP) levels after 28 days of inhalation exposure to rats increased ($p \leq 0.05$) significantly when compared to control. Inhalation exposure of rats to different nitrocellulose paint thinner fumes caused a significant ($p \leq 0.05$) increase in haematological parameters (haemoglobin, packed cell volume and white blood cells) when compared to control group. Rats exposed to "SPRINT®"showed the highest levels of Hb, PCV and WBC with respect to other brands (ABRO®, FIAB®). The order of increase was SPRINT® > ABRO® > FIAB®. Inhalation exposure of rats to paint thinner fumes caused a significant ($p \leq 0.05$) increase in selected biochemical parameters (urea, cholesterol, total and direct bilirubin) when compared to control group. Histological examination of the liver tissues of experimental groups showed degenerative changes in the structural integrity of the hepatic cells. The results suggest that continuous exposure to paint thinner fumes may be hepatotoxic and haemaotoxic in rats and may lead to multiple organ toxicity.

## ET13 - Moving towards a systems biology approach to predictive ecotoxicology

**MO 166**

**Predictive ecotoxicology: predicting responses and physiological consequences to advance the Environmental Risk Assessment of pharmaceuticals**

F Owen, GH Panter, MJ Winter, LB Kinter, R Murry-Smith
AstraZeneca, BRIXHAM, United Kingdom

Human pharmaceuticals detected in aquatic environments have raised concerns about potential impacts on wildlife. These concerns, exemplified by oestrogens, have led the scientific community to address how to predict such effects and how best to advance the Environmental Risk Assessment (ERA) of pharmaceuticals. To better predict potential effects in non-target environmentally relevant species, one area in which our laboratory (amongst others) has been working is the potential use of non-clinical and clinical pharmacological and toxicological data generated during drug development (read-across). Genetic conservation of receptors and physiological systems between mammals and certain environmentally relevant species (i.e. fish), combined with knowledge of primary and secondary Mode-of-Action (MOA) in mammals, can assist in selection of appropriate aquatic test species, study designs, and endpoints in an approach referred to as 'intelligent testing'. Surprisingly, evidence for the proof of this principle is sparse. In this presentation we build on our previous publications[1,2], concerning how best to use the data available from the human drug development, and to address some of the issues surrounding the validation and equivalence of mammalian to fish read-across.

In order to begin to predict the ecotoxicological relevance of the read across model, we need to understand the broader physiological consequences of these predicted effects at each level of the biological system in order to work towards an effective interpretative model. The work presented here reports the first example of the multilayered (systems) approach that we have taken to predict effects and then test the hypothesis via measured endpoints to advance the ERA beyond the current regulatory requirement, in order to provide evidence to support the proof of principle for an intelligent assessment.

**MO 167**

**Linking DNA damage in sperm with reproductive success in adult zebrafish Danio rerio exposed to cobalt (Co2+)**

HC Reinardy[1], J Syrett[1], RA Jeffree[2], TB Henry[1], AN Jha[1]
[1]University of Plymouth, PLYMOUTH, United Kingdom
[2]IAEA Marine and Environment Laboratories, MONACO, Monaco

Toxicants can damage DNA in gametes and the potential for negative consequences in progeny (embryos) may be related to the capability of DNA repair mechanisms. Mature spermatozoa have little or no capability to repair toxicant-induced damage in DNA, and lesions in DNA that are not repaired during spermatogenesis may directly affect embryo survival. By contrast, oocytes retain DNA repair capabilities, and lesions in DNA of oocytes are therefore less likely to affect progeny. The objective of this study was to investigate toxicant-induced DNA damage in zebrafish (Danio rerio) sperm and determine if induction of DNA repair mechanisms are related to reproductive success. Cobalt was selected as an environmentally relevant genotoxicant and initial acute toxicity trials with larvae resulted in an $LC_{50}$ value of 34 mg.l-1 $Co^{2+}$. Adult zebrafish were exposed to sub-lethal concentrations of $Co^{2+}$ (0, 5, 10, 15, 20, and 25 mg.$l^{-1}$). Males and females (n=3 f, n=3 m) were separated in the same tanks (n = 5 treatment tanks, n=3 control tanks) and bulk spawned every 4 days (3 pre-exposure and 3 exposure period spawning events). Prior to exposure 88% of the spawned eggs were fertilized and of these 79% survived to 4 days. Exposure to $Co^{2+}$ significantly reduced the percent of fertilized eggs (5.6%, 25 mg.$l^{-1}$), and survival to 4 d post-fertilization (60%, 25 mg.$l^{-1}$). DNA damage was detected in sperm (sub-lethally extracted and analysed with the alkaline gel electrophoresis 'comet' assay) following 13 d exposure (42% tail DNA, 25 mg.$l^{-1}$ $Co^{2+}$), significantly higher than control (31% tail DNA, dose-dependent increase, p = 0.0041, GLM). After 6 d post-exposure, damage dropped in the top concentration (20% tail DNA, 25 mg.$l^{-1}$ $Co^{2+}$) and there was no significant dose-dependent response (p=0.1902, GLM). Expression of DNA repair genes in testes may lead to repair of DNA in developing sperm and reduction in DNA damage in spermatozoa during the recovery period. We are investigating changes in expression of DNA repair genes (e.g. XRCC5, XRCC6, rad51) in testes of fish from this experiment. The results of cobalt-induced damage, and impaired larval development, show transfer of DNA damage from exposed parent to unexposed offspring. This extends the effects of environmental genotoxicants beyond exposed populations to impaired development in progeny, and the potential for long-term transgenerational effects.

**Conserved toxic responses across phylogenetic divergent lineages: a meta-analysis of the neurotoxic effects of RDX among multiple species using toxicogenomics**

T Habib[1], NG Garcia-Reyero[2], M Pirooznia[3], KG Gust[1], P Gong[1], C Warner[1], MS Wilbanks[1], EJ Perkins[1]
[1]US Army Engineer Research and Development Center, VICKSBURG, United States of America
[2]Jackson State University, JACKSON, United States of America
[3]The John Hopkins University, BALTIMORE, United States of America

At military training sites, a variety of pollutants may contaminate the area originating from used munitions. These contaminants, munitions constituents (MCs), include nitroaromatic compounds such as hexahydro-1,3,5-trinitro-1,3,5-triazine (RDX). RDX has been detected in the environment and several studies have reported toxicity to soil invertebrates at high doses. Studies investigating the mechanism of toxicity of RDX have shown that it affects the central nervous system causing seizures in humans and animals. It has the potential to affect many different species, as they can accumulate and be present in many environmental compartments, thus in a long term may also have evolutionary consequences. In relation to this it is important to establish first how phylogenetically distant species may respond to these types of emerging pollutants. Comparative toxicology and comparative genomics can be used to assess the effects of a contaminant on different species. In this paper, we analyzed the effects of RDX on five different species to elucidate if it elicits effects via common pathways among the species examined. We used a genomics and gene network approach to compare and contrast the neurotoxic effects of RDX among five phylogenetically disparate species: rat (Sprague Dawley), the fathead minnow (Pimephales promelas), earthworm (Eisenia fetida), Northern bobwhite (Colinus virginianus), and coral (Acropora formosa). Our results showed that RDX accumulated into the brain of rat, Northern bobwhite and the fathead minnows. RDX impacted neuronal function in rat, Northern bobwhite and earthworm, but apparently not in fathead minnows. Blood-related impacts were observed in most species. The comparison of Gene Ontology terms indicated several biological processes affected by RDX in all species, such as impacts on calcium signaling (involved in seizure response), effects on xenobiotic metabolism, electron transport, and cell signaling pathways. Overall, the meta-analysis using genomic data of the effects of RDX on several species indicated a common and conserved mode of action of the chemical throughout phylogenetically remote organisms.

## ET16 - Soil ecotoxicology and quality assessment

**Uptake and distribution of metals in maize (Zea mays L.) plants grown in municipal solid waste compost-amended soil**

G Carbonell, M Torrijos, R Miralles de Imperial, MM Delgado, JV Martín, JL García, F Martini, C Fernandez
INIA, MADRID, Spain

The use of municipal solid waste (MSW) compost is a common practice to improve the physical, chemical and biological properties of impoverished soils by supplying organic matter. Community legislation in the EU considers that biosolids may play an important benefit on Climate Change for its action on carbon sequestration and reducing CO2 and atmospheric pollutant emissions. The disposal of the MSW compost may lead to an increase of metal concentration in soil and in consequences, the productivity of crops may be reduced. Data related to the effects of MSW compost on crop performance and metals distribution in maize plant are relatively scarce. Therefore, a greenhouse experiment was conducted in maize (Zea mays L.), with the following objectives: 1) determine the risk of accumulation of total and available metals in soil, as a result of the use of a MSW compost as soil amendment (50 t ha-1) and 2) identify the ability of uptake and distribution of metals to different parts of the maize plant.

The amendment of MSW compost in soil increased the concentrations of Cu and Zn in soil as compared to the unamended soil; however, the rest of metals (Cd, Cr, Ni, Zn and Hg) showed similar concentrations to those found in the control soil. Root system showed the highest metal concentrations and acted as a barrier for all metals. Generally, the trend of metal accumulation was: roots > leaves > stem > cob > sphates >grain.

This study was funded by the Spanish Project CTM 2010-19779-C02-01

**Long-term effect of sewage sludge & compost amendment on soil properties: systematic fertilization versus uncontrolled application**

N Roig Montserrat[1], JS Sierra[1], EM Martí[2], MN Nadal[3], MS Schuhmacher[4], JL Domingo[3]
[1]Universitat Rovira i Virgili, TARRAGONA, Spain
[2]Laboratory of Soil Science, Faculty of Pharmacy, Universitat de Barcelona, BARCELONA, Spain

[3]Laboratory of Toxicology and Environmental Health, Universitat Rovira i Virgili, REUS, Spain
[4]Department of Chemical Engineering, ETSEQ, Universitat Rovira i Virgili, TARRAGONA, Spain
Wastewater treatment processes generate highly biodegradable solid wastes whose final destination is an environmental issue with considerable repercussion for public administrations that intend the sustainable management of the urban wastes. This study aims the advance of knowledge about the effects on environment of the long-term application of sludge and compost in soils in order to enhance their quality and, at the same time, manage this type of wastes in a sustainable way. For that, the analysis of the systematic versus uncontrolled use of sludge and compost as agricultural fertilizers was performed in three regions of Spain. The effects of sludge and compost application were evaluated over some soil physical-chemical properties and functions and also over vegetable growing and pollutants (metals and organics) accumulation.
In general, it was observed that the long-term input of sludge and compost enhances soil properties proportionally to the doses and/or to the frequency of application. The organic amendments increased the organic matter content (and its aromaticity), the soil nitrogen and the microbial activity, improving the mineralization processes of carbon and nitrogen and some enzymatic functions (urease and dehydrogenase). However, there was a maximum dose, from which the soil properties did not show improvement and even decline. Furthermore, it was observed that the repeated and not sufficiently controlled (high doses) sludge and compost amending could be the cause of the imbalance between C and N cycles producing a decrease of the C/N ratio that can involve significant risk for aquifer contamination by nitrates.

**MO 172**

**Dredged sediments use on agricultural land - evaluation using biochemical markers in Eisenia fetida**

E Šuteková, J Priessnitz, J Hofman
Masaryk University, Research Centre for Toxic Compounds in the Environment, BRNO, Czech Republic
High volumes of sediment are removed from Czech rivers, streams and ponds routinely. The subsequent usage of the dredged sediment is an important environmental topic. This material is reach of nutrients and organic matter, but also possibly contains high levels of contaminants. It can be potentially applied as soil improver on agricultural land, but its usage must be regulated based on its contamination or toxicity.
In our study, set of 30 sediments was tested using biochemical markers of oxidative stress and detoxification in earthworm Eisenia fetida. Sediments (samples from rivers, ponds and stockpiles of dredged material ) were chemically analyzed and mixed with reference arable soil in 1:3 ratio (v/v) which has been suggested in novel Czech directive (2009) as realistic scenario after deposition on land. Control groups contained just reference soil. Two different experimental designs using solid matrix (avoidance and reproduction toxicity test) were applied to assess lethal and sub-lethal parametres and to obtain earthworm tissue samples for further biochemical analysis. In earthworms, biochemical markers are often used to observe and evaluate toxic effects of organic and anorganic compounds, or their mixtures, but also influences of other stress resources (pH, physical properties of soils). Therefore biomarkers are suitable sensitive tools to assess effects of real solid matrixes and their mixtures on soil invertebrates. In this study, there were established methods for determination a set of biomarkers (GST, GR, GPX, GSH, lipid peroxidation; coefficient of variation ~ 0,1; ≤ 0,2 for GST, resp.) in earthworm Eisenia fetida used as parametres of oxidative stress and detoxication processes. We observed significant effects (both inductions and inhibitions; One-way Anova and Dunnet test, $p<0.05$) on biochemical parametres comparing to physiological levels of control groups. In both used test designs, GST activity indicated the most sensitive responses. Moreover, our measurements were compared to results of chemical analysis (sum of PAHs, PCBs, DDTs, heavy metals) and other toxicity endpoints as mortality, reproduction and avoidance (Pearson correlation, $p<0,05$; e.g. $r = 0,89$ for GSH subset vs. PCBs in chronic test). Our results confirms suitability of biomarkers as sensitive and simple tools in soil ecotoxicology.

**MO 174**

**Differential sensitivity of soil test species to biochar products**

EAN Marks, X Domene
CREAF - Universitat Autonoma de Barcelona, BELLATERRA, Spain
Biochar is a charcoal product derived from the pyrolysis of biomass, destined for agronomic purposes to improve soil characteristics and fertility. Biochar systems may integrate any combination of uses which include biochar as an agricultural amendment, energy production via byproducts of the pyrolysis process, and carbon sequestration due to biochar's high recalcitrance. However, very little is known about biochar's effect on soil communities, particularly invertebrates for which currently there are no data; therefore the aim has been to provide basic information about biochar's effect on invertebrates, using biological endpoints of ecological significance. Laboratory tests used 3 feedstocks and 3 distinct biochar production methods, and a wide range of biochar-soil mixture concentrations covering all potential application rates. Adult survival and reproduction were evaluated for three soil-dwelling invertebrates of distinct orders and trophic levels; Folsomia candida is a collembolan, Enchytraeus cryticus is an annelid commonly known as the white potworm, and Hypoaspis aculeifer is a predatory mesostigmatic mite. Additionally, germination and growth tests were carried out with Lactuca sativa (lettuce) and Lolium perenne (raygrass). Measured responses were survival and reproduction for arthropods and seed germination and biomass for plants. Results show that organism responses are dependent on all factors considered (feedstock, production method, and organism), with important implications for design and feasibility of biochar systems, the clear message being chars can provoke different biological responses depending on feedstock and/or production method, and that sufficient testing and screening should be carried out before field implementation.

**MO 175**

**Effects of different biochars and their corresponding feedstocks on reproduction and survival of the collembolan Folsomia candida**

X Domene[1], EAN Marks[1], K Hanley[2], A Enders[2], J Lehmann[2]
[1]CREAF-Universitat Autònoma de Barcelona, CERDANYOLA DEL VALLÈS, Spain
[2]Department of Crop and Soil Science, Cornell University, ITHACA, NY, United States of America
Biochar is a carbon-rich product of thermal decomposition of biomass in oxygen-starved conditions, also called pyrolysis. There has been growing interest in the use of biochar as an agricultural amendment, due to biochar´s physico-chemical properties which can greatly improve soil fertility under certain conditions and allow carbon sequestration. However, there is little information about ecological effects of biochar, and to date there are no published studies on biochar effects on soil mesofauna. Furthermore, biochars can vary greatly in their physicochemical properties, and organism responses are hypothesized to vary accordingly. Thus the objective of this study was to answer basic questions about biochar´s potential toxic effects on Folsomia candida, a soil-dwelling collembolan commonly used as a test species in ecotoxicological work. Reproduction and survival assays and avoidance tests were carried out in order to understand how different char materials and concentrations can affect physiochemical properties and influence biological responses of organisms.
Reproduction and survival tests of toxicity with 7 feedstocks and their corresponding low (300-350°C) and high (500-550°C) temperature-produced chars showed that adult survival of F. candida was generally unaffected by any of the factors considered. However, reproductive inhibition was evident for some materials at concentrations > 0.2%, and general inhibition was found for concentrations of 7% and greater which is far beyond recommended application rates which are generally under 1%.

**MO 176**

**In-field evaluation of effects of biochar on soil properties and functions**

X Domene[1], EAN Marks[1], K Hanley[2], A Enders[2], J Lehmann[2]
[1]CREAF-Universitat Autònoma de Barcelona, CERDANYOLA DEL VALLÈS, Spain
[2]Department of Crop and Soil Science, Cornell University, ITHACA, NY, United States of America
Biochar is a carbon-rich product of thermal decomposition of biomass in oxygen-starved conditions, also called pyrolysis. There has been growing interest in the use of biochar as an agricultural amendment, due to biochar´s physico-chemical properties which can greatly improve soil fertility and allow carbon sequestration. Experimental plots in a corn field were established in a temperate region (Aurora, NY) in 2007, with treatments of 0, 3, 12, 30 T/ha, and 1 T/ha corn stover biochar applied annually, all with additions of 90% of recommended N fertilizer. Soil functions and physico-chemical and biological properties were investigated at this site during the 2010 growing season.
It was found that important physico-chemical properties in treatment plots including field moisture, pH and electrical conductivity did not differ significantly from control plots. Total soil respiration did not differ between plots, but microbial biomass in 30 T/ha plots was significantly higher with respect to the control as well as other treatments. In-field three-month decomposition rate, mineralization, and faunal feeding activity were generally found to be unaffected by biochar application rate or frequency, all of which suggests that provision of key ecosystem services is neither impaired by biochar addition of up to 30 T/ha, nor by annual application of fresh char.

The main objectives of the Bioindicator Program is to provide new tools for soil monitoring, characterization and risk assessment, based on soil biological properties. In the first step of this program, research teams have developed and tested their indicator on a few given situations. After selection, the most relevant indicators are now tested and compared on same sites.
This communication presents the first results of the soil fauna working group. Three types of indicator are studied. The IQGS (Global Index of Soil Quality) combine physical, chemical and biological (macro-invertebrates) indicators. A second type deals with measures linked to the structure and/or the diversity of soil invertebrate communities (macro-, meso- and micro-fauna). Last, measures are also realized at organism level (metallothionein coding gene expression in earthworm or metal bioaccumulation in snail or micromammal). These indicators are all tested in 13 sites selected according to their history, their current use and their contamination level.

**Ciliate communities as a tool to assess soil quality in agroecosystem: investigation on agricultural soils under organic farming**

A la Terza[1], B Bharti[1], S Kumar[1], S Marinsalti[1], M Tiberi[2], G Ciabocco[2], E Insom[1]
[1]University of Camerino, CAMERINO, Italy
[2]Osservatorio Regionale Suoli, Servizio Agricoltura, Regione Marche, TREIA (MC), Italy
Ciliated protozoa are ubiquitous eukaryotic microorganisms, which constitutes an essential component of aquatic and soil ecosystems. As single-celled organisms directly exposed to the environment, ciliates are very sensitive to any change in their habitat and fluctuations in their communities can affect the food web and energy transfer within the ecosystem. Thus, the monitoring of the structure of ciliate communities can represent a valuable tool to assess ecosystem quality and functioning. Although the biodiversity and community structure of ciliates has been extensively investigated in freshwater and marine ecosystems, very few studies have been addressed to the analysis of ciliate communities in the soil. The majority of the previous reports mainly regards natural soils such as those of temperate and mangrove forests, and grasslands while, studies on less stable and more potentially "stressed"agricultural soil are very rare and, at least to our knowledge, no studies have been performed on agricultural soil under organic management in Italy.
In our study, ciliates community structures in three fields under organic management located in a hill area (300-550 m asl) of the province of Macerata (Marche) were investigated by means of qualitative (non-flooded method) and quantitative (most probable number) methods. Soil samples were taken twice in autumn and spring. Furthermore, six more sites representative of natural and semi-natural soils, such as forests and grasslands, were sampled for comparison. Physical-chemical as well as pedological data were also recorded. Our preliminary surveys showed a total of 79 species belonging to three classes, 19 orders, 42 genera from all the sites under study. Soil samples showed the dominance of ciliates belonging to genus *Colpoda*, *Gonostomum*, *Oxytricha*, and *Halteria*. The species richness ranged from 37 to 15 and, in agreement with Foissner (1997), is higher in agricultural fields as compared with the natural habitats. This matches the different sites investigated and shows the high bioindicative potential of ciliate species number. This

research represent the first, necessary step toward the development of a molecular profiling assay of ciliate communities in the soil. In fact, the final aim will be that to fruitfully merge taxonomic and molecular data to obtain a more rigorous and detailed picture of the soil ciliate biodiversity.

**MO 179**

**Spatial and temporal distribution of soil microarthropods in in-crop and off-crop habitats**

B Theißen, MI Larnaudie Lopez, M Michala, T Leicher
Bayer CropScience, MONHEIM, Germany

The vertical niche differentiation of soil organisms is an outstanding trait determining the exposure probability to the application of plant protection products. Recently published "EFSA opinions"pointing at the fate of pesticides in the soil compartment, the relevance of the soil litter layer and the soil ecoregion concept take this feature particularly into account. Several studies on the stratification of soil microarthropods (Collembola, Acari) have been conducted yet. But only few concentrated on the situation in agricultural landscapes. Thus until now there is no well-founded knowledge on their vertical dispersal and seasonal fluctuations in arable fields within the course of a year.

We conducted a field study to increase knowledge on the spatio-temporal dynamics of microarthropod-assemblages in the topsoil of both, in-crop and off-crop habitats. In an arable field and an untreated meadow soil cores (5cm in diameter; 5cm and 10cm in depth respectively) were taken monthly, divided into different layers (0-1cm, 1-3cm and 3-5cm and 5-10cm respectively) and extracted for microarthropods by means of heat extraction in a Macfadyen apparatus. The results contribute to a sound development and evaluation of exposure scenarios.

**How do climatic changes affect isopods?**

GC Ferreira, A Amaro, SMV Soares, S Loureiro
CESAM & Dep. Biology, University of Aveiro, AVEIRO, Portugal

Climate changes have been modifying ecosystems, and these modifications will lead consequently to the adaptation or perish of all the organisms that co-habit in those ecosystems.

Organisms like isopods are important key-species to maintain ecosystems function and stability. Isopods as macrodecomposers play an important role in decomposition processes by the fragmentation of litter material and in the re-cycling of nutrients in soil.

To simulate stress induced by global changes, isopods were exposed to ultraviolet radiation, different temperatures, soil moisture levels and pHs.

Biomarkers (e.g. AChE, LPO, GST, CAT, etc.), energy reserves content (lipids, carbohydrates and proteins), energy consumption and cellular energy allocation (CEA) were determined after exposure.

The present work showed that several sub-individual biomarkers activity can be used as early warnings for natural stressors and that climate changes can be responsible for disrupting physiological processes in isopods. This might also be transposed to the ecosystem services considering that the impairment of physiological processes will lead to a less efficiency role on fragmentation of leaf material, decomposition processes and nutrient cycling in soils.

**MO 181**

**A new guideline for the main investigation on soil contamination in the Netherlands**

SAE Kools[1], J Wezenbeek[1], K Grobben[2], S Dijkstra[3]
[1]Grontmij, AMSTERDAM, The Netherlands
[2]Tauw, DEVENTER, The Netherlands
[3]NEN, DELFT, The Netherlands

The national Dutch government initiated the development of a new guideline for the main investigation on soil contamination as an answer to questions from the market. There was a broad wish to use 'second generation' field techniques and to go back to skilled professionals to perform and assess main investigations. In the project of developing the new guideline approximately twenty representatives of stakeholders were involved. The project was performed by two consultancy firms and coordinated by NEN, the Dutch national standardization institute. The new guideline is not a 'cook book' like the earlier protocols, which were never really followed up. Everyone had good reasons to depart from the strict numbers of drillings, groundwater wells and sample analyses those earlier protocols prescribed. The new guideline describes the process to come to a tailor-made strategy for a main investigation. In this way the strategy of a main investigation can be fitted perfectly to the specific local situation, and the most efficient field techniques can be used. The new guideline, in combination with the formalised website with techniques and examples, is aimed at stimulating the use of 'second generation' techniques. In addition, this approach supports skilled professionals in performing main investigations with quality. The presentation will show how to make a guideline that can be enforced, without giving strict rules for the strategy that should be used. A change of mind is needed, to introduce this new way of working. The presentation will show how we try to reach this.

**MO 182**

**Effects of winter road salting on soil microorganisms at grassland and forest site**

J Hofman[1], P Andel[2], E Trávníčková[1]
[1]Masaryk University, Research Centre for Toxic Compounds in the Environment, BRNO, Czech Republic
[2]Evernia, Ltd., LIBEREC, Czech Republic

Road salting is used as a dominant way to keep road safety in winter, even in the protected natural areas. In our study, possible effects of winter road salting on soil microorganisms in close road vicinity were investigated. Soil chemical and microbial properties were monitored at forest site in Krkonoše Mountains national park and at grassland site in Kokořínsko protected landscape area in two sampling campaigns (autumn and spring). Effects of road salting on soil chemical properties (Na+ and Cl- levels, pH, base saturation [3DOTS]) were clearly apparent. The most affected plots were 1 and 5 m from the road. At these plots, some changes of microbial parameters were observed in both autumn and spring sampling, which suggested influence of salts. Hence, possible influence on soil biological quality should be considered when assessing the ecological risks of this kind of road treatment, especially in natural protected areas.

**MO 183**

**Contamination, ecotoxicity, microbial and physico-chemical properties of soils in frequent urban roads surrounding**

J Hofman[1], P Andel[2], J Bezchlebová[1], J Cernohlávková[1], J Lána[1], I Sochová[1], K Kobeticová[1]
[1]Masaryk University, Research Centre for Toxic Compounds in the Environment, BRNO, Czech Republic
[2]Evernia, Ltd., LIBEREC, Czech Republic

Intensive traffic has influence on surrounding ecosystems and one of the most important target of this influence is probably soil. In our study, model localities were selected in the surrounding of very busy roads in Prague city. Samples were taken on the roadside and 10-30 meters from the road. Control samples were taken in the Prague city but at significant distance from any busy road (urban background). In the samples, main physico-chemical properties were analysed as well as contamination with heavy metals and organic pollutants (PAHs, PCBs, HCB ...). Microbial parameters of soil were also evaluated. All samples were tested for toxicity using standard soil bioassays with Eisenia fetida, Enchytraeus crypticus, Folsomia candida, Caenorhabditis elegans. The objectives of the study were: 1) to investigate if there are some relationships between contamination of soils and traffic intensity, 2) to investigate the relationships between soil contamination, soil properties, microbial parameters and toxicity in soil bioassays. The results showed increased PAHs at the roadside, but heavy metals at the roadside and further from the road were comparable. No clear relationship between traffic data and contamination was observed. Also effects of soil contamination on soil microbes or model organisms were not apparent. These results show that whole problem (of soil load by traffic and consequent effects on ecosystem) is more complicated. In complex approach, measurement of other factors must be integrated (e.g. local conditions affecting the entry of contaminants to the soil, accumulation properties of soil, bioavailability characterization etc.).

**MO 184**

**Accumulation of metals in vegetation and invertebrates in polluted ecosystems of Flanders**

MC Boshoff, L Bervoets
University of Antwerp, ANTWERP, Belgium

Soil often acts as the ultimate 'sink' of environmental pollution, because clay minerals and humic materials have a large number of surfaces, chemical groups and organic particles to which pollutants can attach. The concept of soil metal bioavailability refers to metal fractions in chemical forms which can be taken up by different soil organisms and by plants. The ultimate measure of metal bioavailability is the uptake thereof in organisms and vegetation. If a contaminant is found inside an organism it must have been bioavailable while the accumulated concentration can be related to adverse effects. Soil, vegetation and invertebrates were collected over a period of 11 weeks in the region of Antwerp, Belgium. This was done in order to assess the relationship between soil characteristics and the level of bioavailability of metals in contaminated soils. Sampling took place along an historical metal pollution gradient. The following parameters were measured: Soil (pH, CEC, clay %, moisture %, CaCl2, metal concentration in soil mineral fraction and pore water), vegetation (metal concentrations in mono-/dicotyle plants) and invertebrates (metal concentrations in primary, secondary and tertiary consumers). Furthermore, we search for a hierarchical correlation between the species' position in the food web and the level of heavy metal accumulation by performing C/N stable isotope analysis.

**MO 185**

**The effect of natural disturbances on microbial properties in heavy metal polluted soils**

J Morawska-Ploskonka, D Ploskonka, K Kozupa, M Chodak, M Niklinska
Jagiellonian University, KRAKÓW, Poland

Soil microorganisms play an essential role in the decomposition of organic matter. A large number of studies have indicated that soil microbes from polluted sites reveal heavy metal resistance. In such environment every additional stressor may disturb the structure of microbial community and have adverse consequences on the whole soil ecosystem. The effect of single stressor on the soil microorganisms has been well elaborated, but only limited research has been carried out to test the effect of simultaneously acting diverse stressors.

Aim of the study was to estimate the effect of interactions between long term heavy metal pollution and natural factors (temperature fluctuations and drought stress) on soil microbial communities.

Samples of the O horizons were taken at 5 sites along pollution gradient located near Zn-smelter in Poland. The samples were acclimated under optimal conditions (22oC, 50%WHC) for a week, placed under stressing conditions (temperature fluctuations: 20oC /30oC per 12h, drought) for eight weeks and then incubated again under optimal conditions for six weeks. Microbial properties were measured prior to the stress period, directly after it, two and four weeks after the stress period. Measured were basal respiration rate (RESP), microbial biomass (Cmic), nitrogen mineralization rate and urease activity. Heavy metals and stress period affected RESP, but did not affect Cmic. Drought and elevated temperature period significantly increased RESP, resulting in higher values of metabolic quotient ($p<0,005$). Highly polluted soils exhibited lower RESP. Urease activity increased after the stressing period ($p<0,005$), however the increase was less pronounced in the polluted soils. The stressing period did not affect the contents of NH4+ and NO3- but increased the contents of NO2- ($p<0,005$) in the studied soils. The obtained results indicated that long term heavy metal pollution modifies the reaction of soil microbes to additional stressing factors. We presume that the observed changes in RESP, URE and NO2- after the stressing period were due to changed C and nutrient availability.

**MO 186**

**Zn, Cu, Pb and As accumulation in Brassica oleracea cropped in contaminated soils**

PJC Favas
University of Trás-os-Montes e Alto Douro, VILA REAL, Portugal

We present a synthesis of the data obtained from the survey, in order to assess the contents of some chemical elements (Zn, Cu, Pb and As) in the soils and in exemplars of horticultural species (Brassica oleracea L. var. oleracea) collected in the area around the tailings of Jales Mine (Vila Pouca de Aguiar, Vila Real, Northern Portugal), taking as a reference exemplars from a location somewhat removed from the mine and therefore less exposed to aeolic dispersion of dust released from it.

In each area we established 5 sampling spots. The soils samples were collected to the depth of 20 cm. The vegetal material sampling fell upon the whole plant and we proceeded to the separation of the different organs (roots, stalks and leaves). The techniques used for chemical analysis involved incineration until everything was reduced to ashes. Then we proceeded to an acid attack over this material, followed by the analysis through Atomic Absorption Spectrophotometry (AAS) to determine Cu and Zn, resorting to the Graphite Chamber to determine Pb and As. The exemplars of Brassica oleracea L. collected in the areas of contaminated soils accumulate heavy elements and arsenic in higher amounts than the ones observed in the exemplars collected in the regulating area. The values accumulated in the plant that we analysed change between 11 to 147 mg kg-1 for Zn, between 1.5 to 5.6 mg kg-1 for Cu, between 2.4 to 7.3 mg kg-1 for Pb and between 1.62 to 11.15 mg kg-1 for As. The contents of Zn, Cu and Pb are within the normal patterns in plants (Kabata-Pendias and Pendias, 1984). The contents of As are above the limits (Adriano, 2001), pointing out to a strong contamination at the biological level.

**MO 187**
**Use of the bait lamina test to assess the effects of lead contamination on the soil organisms of a shooting range**

S Campiche[1], A Zumbühl[2], C Gachet Aquillon[1], E Grand[1], I Werner[1]
[1]Swiss Centre for Applied Ecotoxicology Eawag-EPFL, LAUSANNE, Switzerland
[2]Zürcher Hochschule für Angewandte Wissenschaften (ZHAW), WINTERTHUR, Switzerland

In Switzerland, assessment of soil pollution is mainly based on chemical analysis of total or soluble content of specific contaminants. Methods assessing soil biological parameters have been proposed to complete the chemical parameter data. Currently, no ecotoxicity tests are employed to assess soil contamination in the field. In order to propose and integrate ecotoxicity tests for soil protection in Switzerland, the use of functional methods such as the bait lamina test is considered for the monitoring of pollution gradient at contaminated sites. In the present work, the bait lamina test was applied at an outdoor shooting range as high lead (Pb) concentrations were found at this site. Changes in overall feeding activity of soil organisms were measured in 4 areas along the Pb gradient of contamination to assess the potential impact of this metal on the soil biocenosis. The bait lamina results were complemented by physico-chemical analyses of soil and by reproduction tests with collembolans on collected field samples. Pb concentrations (pseudo-total content) in soil along the contamination gradient ranged from 40 mg/kg (control area) to 2900 mg/kg for the most contaminated area (target and impact berm vicinity). The overall feeding activity of soil organisms after 46 days for the 4 areas varied between 14% and 20%. The high Pb concentrations found in soil near to the targets and impact berm did not seem to influence the feeding activity of soil organisms when compared to the one observed at the control area. This may be explained by the low Pb bioavailability measured in the analyzed soil samples. In the future, the bait lamina method will be further optimized and additional tests will be conducted at contaminated sites to assess the applicability of this method for the risk characterization of contaminated sites in Switzerland.

**Quality assessment of soils from S. Domingos Mine (Portugal): chemical, biochemical and ecotoxicological evaluation**

PM Alvarenga[1], PA Palma[1], P Lourenço[2], R Folgado[2], AP de Varennes[3], AC Cunha-Queda[4]
[1]Polytechnic Institute of Beja - Agricultural Superior School, BEJA, Portugal
[2]CEBAL, Centro de Biotecnologia Agrícola e Agro-Alimentar do Baixo Alentejo e Lit, BEJA, Portugal
[3]DQAA - Instituto Superior de Agronomia, TU Lisbon, LISBON, Portugal
[4]UIQA-UIQA - Instituto Superior de Agronomia, TU Lisbon, LISBON, Portugal

S. Domingos Mine is an abandoned mine located in the Portuguese sector of the Iberian Pyrite Belt. This study presents results obtained for the quality assessment of soils collected in three different locations of the mine area considering: chemical characterization; pseudo-total trace element quantification and their water-leachable fractions (As, Cd, Cr, Cu, Ni, Pb and Zn); ecotoxicity evaluation (plant growth and germination tests with Avena sativa L. and Brassica rapa L., Eisenia fetida mortality, E. fetida avoidance behaviour, luminescent inhibition of Vibrio fischeri and Daphnia magna immobilization); soil enzymatic activities (dehydrogenase, β-glucosidase, cellulase and acid phosphatase) and soil total bacterial DNA quantification. The soils were acid, poor in organic matter and in plant nutrients. Soil A has higher As and Pb content, while soil C has higher Cu and Zn concentrations. B. rapa was more sensitive than A. sativa to this type of soil contamination, and they both allow the classification of soil C as the most toxic. E. fetida mortality was the least sensitive of the direct bioassays used. On the contrary, the behavioural response bioassay, with the same organism, was found to be an extremely sensitive endpoint, allowing the classification of these soils has toxic or with impaired quality, as less than 20% of the organisms were found in the test soil for concentrations above 6.3% (v/v) for soil A and B, and 4.7% for soil C. In the aquatic bioassays, D. magna evidenced as a more sensitive organism to this type of soil contamination, with an EC50 of 3% (v/v) for the leachate from soil C, more toxic than soil B (12% v/v) and soil A (23% v/v), than the luminescent bacteria bioassay, that also allowed the confirmation of the leachate from soil C as considerably toxic. Results from the soils enzymatic activities and from the total bacterial DNA quantification identified soil B as the one containing higher quantity of DNA and higher enzymatic activities. The results from the aquatic bioassays confirmed the soil toxicity categorization obtained with the bioassays testing the whole soil: soil C was found to be the most toxic. Even though, results indicate impaired soil retention function and habitat function for all soils that were evaluated, highlighting the need for a soil intervention at the site.

**Landfill impact zone on soils using structural and functional modifications of microbial communities**

TO Poputnikova[1], VA Terekhova[2], AS Yakovlev[1]
[1]Moscow State University, MOSCOW, Russian Federation
[2]Severtsov Institute of Ecology and Evolution, MOSCOW, Russian Federation

An urgent problem is the identification of zones of actual and potential ecological risk from the waste industry. Ecological regulation in Russia uses the scale based on MPC ranking. Effectiveness and informativity of indices used for zoning of the territory adjacent to waste disposal sites are distinct from each other.

We have attempted to perform zoning of the territory adjacent to the landfill (Moscow region), in accordance with variability of the structural and functional parameters of microbial communities. The influence of the landfill as an environmental pollutant on adjacent soils is found to stimulate the soil microbiota development, growth of population, biomass and biological diversity, increased spore fungi biomass, and activation of soil respiration (data received from gas chromatography/mass spectrometry analysis, luminescence microscopy, specimen inoculation on Chapek agar media, $CO_2$ emission).

The methods applied here determine the impact of the landfill at different distances. Based on the degree of difference in the described indices from the background at different locations down gradient of the landfill, we arranged them from decreasing soil sensitivity to leachate pollution as follows: relative population of soil fungi calculated directly (luminescence microscopy) or by inoculation; total fungi biomass > soil respiration; species diversity of bacterial biomass; total bacterial biomass > spore fraction in the fungal biomass.

To generalize the obtained data and zone the territory, the disturbance index was calculated, representing the deviation of the biotic indices population in the studied samples from the background.

If the total soil pollution by heavy metals at 950 m (in the predominant direction of pollutant migration) is permissible, a 30% difference from the background (conforming with the norms for total indices) can be detected by biological methods only at 1500 m from the landfill, i.e., outside the sanitary protection zone of the landfill (500 m).

**MO 190**
**Detoxifying action of humates towards phosphogypsum**

OS Yakimenko[1], AA Izosimov[1], MA Kanis'Kin[1], VA Terekhova[2]
[1]Moscow State University, MOSCOW, Russian Federation
[2]Institute of Ecology and Evolution, MOSCOW, Russian Federation

Phosphogypsum (PG) is a side product in industrial production of phosphoric acid, which is obtained by a treatment of phosphatic raw materials or apatites with a mixture of sulfuric and phosphoric acids. Due to high content of nutrients (calcium, phosphorus and sulfur) it is sometimes used as a fertilizer for poor unfertile soils. But besides nutrients, PG also contains toxic impurities, such as fluorine, strontium and some others. One of contemporary tools to reduce the ecotoxicity of polluted soils and soil-PG mixtures is an application of humic substances (HS). In nature HS are formed in soils, natural waters, bottom sediments, peat and lignite. Nowadays industrial companies produce HS or humates from organic raw materials, mostly lignite and peat. Being the natural organic high-molecular polymers of irregular structure, humates have been showed as substances capable to decrease the toxic effects of pollutants in soils.

The objective of this study was to evaluate the detoxifying ability of a number of humates towards PG applied to model soil mixtures.

Materials and methods. Model soil mixtures (MSM) contained 20% of kaoline, 10% of peat and 70% of sand (ISO 11268-1). PG was carefully mixed with MSM at concentration 3.3 and 7.5%; and humates from peat (Pe-FlexK, Pe-EcoK), coal (BC-EnK, BC-HumNa) and lignosulphonate (OW-LhK) were applied as 0.005 and 0.020% water solutions. Obtained mixtures were incubated during 10 days at 25°C and the ecotoxicity was evaluated using three standardized test-reactions of organisms from different trophical levels and taxonomic groups: microalgae *Scenedesmus quadricauda*, crustaceans *Daphnia magna*, and higher plants *(Sinapis alba)*. Toxicometric parameters ($EC_{50}$ and no observed effect level NOEL) and detoxification factor D were calculated.

Results. Analyses of average detoxification factors $D_{av}$ showed that influence of humates depended both on PG concentration and humates' nature. Thus, application of PG at concentration 7.5% was toxic for all the test-cultures at all treatments and humates were not able to decrease the toxicity. At lower rate of PG (3.3%) some humates decreased the toxicity ($D_{av}$ is 0.4-0.8), whether other did not. Among all humates tested the highest detoxifying ability was observed for two samples: Pe-FlexK from peat and BC-EnK from coal. For these humates EC50 and NOEL values increased in 1.3 - 1.8 times for *S. quadricauda*, 1.1 - 1.4 times for *D. magna* and 1.6 - 2 times for *S. alba*.

**MO 191**
**Large Hg pollution of surface waters and sediments due to a chloro-soda industrial plant located in the northeast of Italy**

G Perin[1], F Avezzù[2], A Cecchin[3], A Giacometti[2]
[1]IDEAS Centre - University of Venice - Archives of Environmental-Human Toxicology, VENICE, Italy
[2]Environmental Science Dept - University of Venice, VENICE, Italy
[3]IDEAS Centre - University of Venice, VENICE, Italy

Since 1979, a chloro-soda industrial plant located in the northeast of Italy discharged an amount of Hg comprised between a minimum of 25 and a maximum of 7200 kg per year. A severe surface water and sediment Hg contamination resulted in the surrounding environment, reaching a contamination peak of 300 g per kg of dry sediment. Research pursued by scientists demonstrated sediment pollution in those rivers and water bodies receiving such industrial wastewaters. Pollution migrated downstream, soon reaching a large lagoon close to the Adriatic Sea. Lagoon mussels and fishes were effected, and probably also those of Adriatic Sea as well. Being the lagoon environment naturally suffering Hg presence, a special analytical technique was necessary to distinguish between anthropogenic pollution vs. natural background Hg. Such technique, called 'Cavelli Method', allowed to precisely identify which lagoon areas were effectively polluted by Hg of industrial origin. After 1989, a higher environmental sensibility produced a drastic reduction of Hg output, ensuing 10-fold lower emissions. This showed the effectiveness of pollution containment policies and regulatory enforcements as well as the feasibility of environmental recovery.

**Effects assessment of cobalt in the terrestrial environment**

K Oorts[1], P van Sprang[1], W Stubblefield[2], E Smolders[3]
[1]ARCHE, GENT, Belgium
[2]Department of Environmental and Molecular Toxicology, Oregon State University, CORVALLIS, United States of America
[3]Division Soil and Water Management, Katholieke Universiteit Leuven, LEUVEN, Belgium

The toxicity of metals in soils is affected by a number of factors such as species sensitivity, soil physicochemical properties, and ageing processes. We conducted an evaluation of Co toxicity to a variety of terrestrial organisms in soils; specific consideration was given to the effect of soil properties and ageing on Co bioavailability and toxicity. In total 127 individual reliable chronic toxicity studies with Co were identified from the literature or from our own empirical studies. Available chronic data included a total of 7 higher plant species (covering both monocotyledons and dicotyledons), 4 invertebrate species (covering both arthropods and non-arthropods) and 3 microbial processes (for both C- and N-cycles). Chronic toxicity data were identified from studies run in 13 separate soils displaying a range of soil properties typical of those found throughout Europe, and after varying equilibration times up to 12 months after spiking with $CoCl_2$. In general, higher plants were found to be most sensitive to Co in soils, while microbial processes were least affected. Laboratory studies showed a 10- to 100-fold variation in chronic toxicity among the various soils tested. Chronic Co toxicity best correlated with the effective CEC (eCEC) of the soil, with toxicity decreasing as a function of increasing eCEC. Linear regression models based on eCEC explained between 59-97% of the variability in Co EC50 for the terrestrial organisms. Ageing of Co-amended soils resulted in decreased Co bioavailability and chronic toxicity. However, the mitigating effect of ageing was noted to decrease with decreasing pH. This observation was confirmed by changes in availability of Co in the soils with time determined by an isotopic dilution procedure. After correction for differences in bioavailability of Co among the available chronic toxicity data, soil-specific Predicted No Effect Concentrations (PNEC) were derived from a species sensitivity distribution. Cobalt PNEC values ranged between 5 and 50 mg Co/kg soil for relevant soil conditions in Europe.

**MO 193**
**Effects assessment of boron in the terrestrial environment**

K Oorts[1], P van Sprang[1], MC Harrass[2], I Schoeters[3]
[1]ARCHE, GENT, Belgium
[2]Rio Tinto Minerals, SCHAUMBURG, ILLINOIS 60195, United States of America
[3]Rio Tinto, LONDON, United Kingdom
Boron is a naturally occurring trace element that is essential to a variety of organisms. This poster will describe the available data considered in developing a soil PNEC for boron using the REACH framework. In total, more than 200 reliable individual NOEC or EC10 values were selected for 28 different plant species (covering monocotyledons and dicotyledons), 9 different invertebrate species (including worms, nematodes, collembola, insects and mites) and 2 microbial processes. Plants are generally the most sensitive group to added boron. These data supported the development of a species sensitivity distribution (SSD) and estimation of the HC5 value. Data screening based on relevance was found to be as important as screening for study quality (e.g., Klimisch score) in the evaluation of boric acid and sodium borates. Much of the published research is focused on avoiding B deficiency for crop plants and other publications reported tests in hydroponic or sand/water conditions. Although many of these studies are scientifically valid and perhaps technically stronger than standardized ecotoxicity studies, with longer duration, additional endpoints and testing under field conditions, these data were excluded from the SSD. However, some of these data were still used as supporting evidence in the uncertainty analysis on the HC5 value. Some plant data suggested a narrow range between deficiency and toxicity of boron in soil, with beneficial effects on some species occurring at concentrations associated with adverse effects in others. The bioavailability of many elements varies substantially with soil properties. Limited studies with plants and boron added to soil suggest that added boron will likely be both bioavailable and mobile. Soil properties seem to modify these properties relatively little in the short term and, in general, are less than the variation among species. Bioavailability was therefore not used to modify the effects assessment. An added risk approach was selected because of the narrow range between deficiency and toxicity of B in soil, and the significant difference in solubility between added B and B naturally present in soils.

## MO 194

**Effects of silver on the terrestrial isopod Porcellionides pruinosus**

PS Tourinho[1], CF Calhôa[1], AMVM Soares[1], CAM van Gestel[2], S Loureiro[1]
[1]University of Aveiro, AVEIRO, Portugal
[2]Vrije Universiteit, AMSTERDAM, The Netherlands
Silver is a trace element that occurs at low levels in the environment. However, silver contamination has increased due to anthropogenic inputs, such as industrial activities and sewage treatment plants. As the bioavailable silver can be toxic, studies are required to predict the potential risks in soils. Terrestrial isopods are suitable indicators for assessing the ecotoxicological risk of metals in soils due to their extraordinary capacity to bioaccumulate toxic metals from the environment in their body (i.e. hepatopancreas). In this study, we aim to assess the toxic effects of silver ($AgNO3$) on the terrestrial isopod Porcellionides pruinosus. For this purpose survival, avoidance behavior and feeding activity endpoints were analyzed. For the survival and avoidance tests, Lufa 2.2 soil was used as exposure medium and lethal effects were observed after 7 and 14 days and avoidance after 48 hours. For the feeding inhibition test, a mixture of finely-ground alder leaves and Ag-contaminated gelatin were selected as a suitable food substrate to expose the isopods for 14 days. The lethal concentration for 50% of the isopods (LC50) was 726 mg Ag kg-1 dry soil after 7 days, which decreased to 398 mg Ag kg-1 soil after 14 days. In the avoidance test, the avoidance concentration for 50% of the animals (AC50) was 8.79 mg Ag kg-1 dry soil. In the exposure to Ag via food, a significant impairment of feeding parameters (e.g. food consumption, assimilation and excretion) was observed during the 14 day exposure, but data still have to be analysed. The avoidance endpoint was more sensitive to Ag exposure than lethality. Feeding impairment might be an indication for ecosystem disruption by Ag contamination.

## MO 195

**Life table response experiments with two species of Collembola**

JB Schmidt, M Meli, A Palmqvist, VE Forbes
Roskilde University, ROSKILDE, Denmark
Collembola are an integral component of soil ecosystems as decomposers of organic matter or part of the food chain and are vulnerable to effects of soil contamination. Their presence in all types of soil and their importance to soil biology as well as their ease of handling has made them an important and widely used species for ecotoxicological testing. Standard experimental procedures currently focus on reproduction or survival over a short time period starting with half mature juveniles. Both growth and reproduction, as well as survival, of the organisms are essential for maintaining populations, and therefore biological impacts of soil contamination should be investigated from a life-cycle perspective.

Here we present results of life table response experiments performed on two species of Collembola that differ in their reproductive strategy. Cohorts of parthenogenetic *Folsomia candida* and sexually reproducing *Sinella curviseta* were exposed to a heavy metal via soil, soil surface and food on a plaster of Paris mixture in different test setups. The experiments are easily conducted and enable constant observation of the organisms and analysis of additional life-cycle variables to gain insight into the individual-level mechanisms resulting in population-level impacts. Simple population models were used to derive population growth rate as a summary statistic to measure toxicant induced fitness reduction and to link individual performance of the springtails to population dynamics. Outcomes from elasticity analysis on the population growth rate suggest that more attention should be given to the earlier life stages of Collembolans during ecotoxicity testing given the importance of these life stages for population dynamics.

The advantages and limitations of the experimental methods and different exposure routes will be addressed. The results, their implications for testing different life histories and implications for further experimental work are discussed.

## MO 196

**The toxicity of silver (Ag) to soil-dwelling organisms: plants, earthworms, springtails and soil micro-organisms**

R Velicogna, J Princz, E Ritchie, J Gauthier, A Okonski, R Scroggins
Environment Canada, OTTAWA, Canada
To support the Federal Government of Canada's Chemical Management Plan, soil toxicity tests were conducted to evaluate the inherent toxicity of silver (as silver nitrate) to a suite of terrestrial species, as well as the soil microbial community. Silver was identified as a medium priority inorganic substance requiring further evaluation from a screening assessment perspective, due to uncertainties relative to environmental persistence, bioaccumulation and inherent toxicity. The lethal and sub-lethal toxicity of silver was determined for the earthworm, Eisenia andrei, then collembolan, Folsomia candida, as well as two plant species (Trifolium pratense and Elymus lanceolatus). The tests were conducted according to standardized Environment Canada soil toxicity test protocols, using a field-collected sandy-loam soil. The effect of this substance to the soil microbial community (e.g., microbial activity, biomass and temporal shifts in the soil microbial community) was also investigated using the same soil type. The data derived from this research project will supplement and verify the PBiT (e.g., inherent toxicity) status of this compound, and will support Canada's effort in the screening assessment of this medium priority compound.

## MO 197

**The use of earthworm metal content in highest tiers of a site environmental risk assessment in the tropics**

JC Niemeyer[1], TMF Natal Da Luz[1], J Pratas[2], EM Da Silva[3], JP Sousa[1]
[1]University of Coimbra, COIMBRA, Portugal
[2]Depart. Ciências da Terra, University of Coimbra, COIMBRA, Portugal
[3]Instituto de Biologia, Universidade Federal da Bahia, SALVADOR, BAHIA, Brazil
The highest tiers of an environmental risk assessment should involve accurate site investigation on the risk of contaminants for specific routes of exposure. The results that will be presented were obtained in an environmental risk assessment carried out in an abandoned lead smelter in Santo Amaro, Brazil, which is an area contaminated predominantly with copper (Cu), cadmium (Cd), lead (Pb) and zinc (Zn). In this assessment, metal-contaminated soils were collected along two transects making a gradient of natural metal-contaminated soils, starting from a central point located next to smelter facility and up to 3Km. Aiming to obtain information on the bioavailability and bioaccumulation of metals to earthworms in the study area, five adults of Eisenia andrei were exposed to some of the metal-contaminated soils collected, three reference natural soils and the OECD artificial soil for 6 weeks under laboratory conditions. At the end of this period, the concentrations of Cu, Cd, Pb, and Zn were measured in soil and earthworms (using 69% $HNO3$ extractions) by AAS-flame. In reference soils, the concentrations of Cu, Cd, Pb, and Zn in earthworms were on average $11 \pm 3$, $3 \pm 0.5$, $21 \pm 7$, and $134 \pm 14$ mg/kg, respectively. In metal-contaminated soils the highest concentrations of Cu, Cd, Pb, and Zn in earthworms were on average $219 \pm 454$, $251 \pm 34$, $1049 \pm 235$, and $839 \pm 338$ mg/kg, respectively. Results demonstrated that lead was the most bioavailable metal as expected, followed by Zn. It was also evidenced that there is risk for higher trophic levels up the food chain. In this contribution, the sensitivity of this parameter and its value in the TRIAD within a site ERA scheme are discussed.

## MO 198

**Higher tier assessment of a metal contaminated area in the tropics: the impact on leaf-litter breakdown**

JC Niemeyer[1], GG Rodrigues[2], EM Da Silva[3], JP Sousa[1]
[1]University of Coimbra, COIMBRA, Portugal
[2]Dept. Zoologia, Centro de C. Biológicas, Universidade Federal de Pernambuco, RECIFE, PERNAMBUCO, Brazil
[3]Instituto de Biologia, Universidade Federal da Bahia, SALVADOR, BAHIA, Brazil
Litter bag test is considered the most appropriate method available for assessing organic matter breakdown in semi-field or field conditions. As a part of an environmental risk assessment carried out in an abandoned lead smelter in a tropical area from Santo Amaro, Bahia, Brazil, presenting high levels of metal contamination, this test was used in the higher tier assessment, as part of the Ecological LoE of a TRIAD approach. Percentage of remaining mass loss of Schinus terebinthifolius Raddi (Anacardiaceae), a native tree species, was determined in contaminated and reference sites. A total of 192 leaf-litter bags were exposed in October 2009 on the soil surface in all the 12 sampling points considered. Four leaf-litter bags from each plot were collected randomly at each period (15, 43, 83 and 131 days). Treatment of samples, calculations of results and correction factors were carried out according to OECD 2006 draft protocol. When comparing to reference sites, results showed the impairment of leaf-litter decomposition in sites inside the smelter area (most contaminated sites), which may pose a risk to ecosystem functioning. Besides the direct effects of metal contamination, this functional endpoint reflects the damage to the overall ecological status of the site, probably originated by physical characteristics of tails deposits, such as low water holding capacity and low humidity, low vegetation cover and consequently loss of suitable habitat for soil invertebrates and microorganisms. In this contribution, the sensitivity of this parameter and its value in an ERA scheme are discussed.

## MO 199

**A novel ecotoxicological method: the effect of cadmium on pathogen resistance of Arabidopsis thaliana**

N Yamamoto, A Nakayama, K Kenichiro, M Minoru
Kyoto Universiry, KYOTO, Japan
Ecological risk assessment method has not yet been established. Although there is rising public concern that the contaminants in soils might affect ecosystem as well as human health, ecological risk assessment method has not yet been established. The technical barrier to establish risk assessment is to define endpoints that can detect the effect of contaminants in soil quantitatively. Among soil organisms, plants are responsible for primary productions for all the life on earth. A decrease of plants causes severe repercussions on whole ecosystem. Developing the ecotoxicological methodology using should have a higher priority.

We have been trying to detect the effect of cadmium in various points on Arabidopsis thaliana and found they are susceptible to pathogens. In view of this, we made the assumption that the contaminants in soils may effect on the pathogen resistance of plants and it could cause adverse impacts on ecosystems.

In this study, we try to develop a method to assess the pathogen resistance quantitatively using Arabidopsis thaliana exposed to cadmium. In order to assess pathogen resistance, we inoculated the plant pathogen, Alternaria brassicicola, onto the leaf of cadmium-exposed Arabidopsis thaliana, and then investigated the relationship between cadmium exposure and incidence and extent of the disease. Incidence of the disease was found to be higher in cadmium exposed-plants than in unexposed group. Also there was a dose-dependent increase in necrotic leaf area. These results show that cadmium exposure reduced pathogen resistance of Arabidopsis thaliana. Thereby, we defined "Pathogen resistance factor"to perform a quantitative assessment of effect of cadmium on pathogen resistance of Arabidopsis thaliana. Pathogen resistance factor is expressed as a quotient of the necrotic area ratio to the whole leaf area exposed to cadmium divided by that of unexposed. Pathogen resistance factor decrease to 0.37 and 0.23 by 0.5 and 1 microM cadmium exposure, respectively.

Pathogen resistance factor could be used for quantitative ecotoxicological assessments.

## MO 200

**Genotoxic effects of Boron contaminated sediments from Cecina basin (Tuscany) on Vicia faba L.**

L Giorgetti, M Barbafieri

CNR, PISA, Italy

In this work a Boron contaminated sediment from the Cecina basin in Tuscany (Italy) was considered for its possible genotoxic effect on plants. The greatest part of Cecina basin is located in the geothermal zone of Larderello, where for about a hundred years the mine activities in this area and more recently the geothermoelectric industry spilled in the Possera and Pavone creeks (tributaries of Cecina River) until about 1975. However, contamination is still present in certain areas of the basin with high level of B.

Two samples with different B content were used in phytotoxicity studies: A) with high B concentration of 108 mgkg-1 as total and 43.3 mgkg-1 as bioavailable, B) with 69.8 and 22.8 mgkg-1 respectively as total and bioavailable content.

Previous studies demonstrated that both excess or deficiency of B can affect normal plant growth and as a consequence agricultural production thus the effects of B contaminated sediment were analyzed considering seed germination, root elongation and mitotic division in root tip cells of Vicia faba L., which is commonly used for detecting the genotoxic effects of environmental pollutants.

Seeds of Vicia faba L. were germinated in contaminated sediment and cytological analysis and root tip micronucleus assay (MNC), were performed after 3 days (primary roots) and after 10 days (secondary roots) for genotoxicity evaluation.

The results clearly indicated B toxicity since the length of the primary root and the size of Vicia plants were significantly reduced when compared to control plants. Cytological analysis on primary root tips (3th day) showed no effect on mitotic activity of meristematic centers but a big presence of micronuclei was found (a frequency of 5% of micronuclei in contaminated soils compared to 1% in control). Moreover mitotic anomalies, as chromosome bridges, chromosome lagging and c-metaphases, were found. The analysis on secondary root tips at 10th days from germination confirmed the presence of mitotic anomalies at a higher extent and different behavior of meristematic center was observed since mitotic index (MI) was reduced in root tips from B contaminated soils (MI = 9,3%) when compared to control (MI = 17,7%) but no micronuclei were found. This results indicated the phytotoxicity of B contaminated sediment of polluted area of Cecina. B concentration in soil is a very critical point and more attention should be done on environmental contamination by industrial activity and wastewater pollutants.

**MO 201**

**Earthworms' in situ exposure and evaluation of genotoxicity endpoints to assess the toxicity of uranium mining wastes**

I Lourenço[1], RO Pereira[1], AC Silva[1], FP Carvalho[2], JO Oliveira[2], MP Malta[2], AA Paiva[3], FJ Gonçalves[1], SA Mendo[1]

[1]University of Aveiro, AVEIRO, Portugal

[2]Instituto Tecnológico Nuclear, LISBOA, Portugal

[3]Centro de Histocompatibilidade do Centro, COIMBRA, Portugal

The exploitation of radioactive ore in Portugal lasted from 1908 to 2001, and took place mainly in the centre-north of the country (Carvalho et al. 2009a). The uranium extractive industry generated considerable volumes of wastes often containing high concentrations of toxic metals and radionuclides (Antunes et al. 2008a). Toxicity assays conducted under controlled laboratory conditions, lack the integration of natural fluctuating environmental conditions (Moreira et al. 2005). Consequently, it could be difficult to extrapolate laboratory results to field situations, especially when radioactive environments are considered. By integrating natural fluctuating environmental conditions, in situ assays allow more realistic exposures (Moreira et al. 2005).This study aimed to assess the applicability of the earthworms reproduction assay (OECD 2004) and the evaluation of the geno and citotoxicity endpoints in in situ exposures of Eisenia andrei Bouché to radioactive uranium wastes. In parallel, the bioaccumulation of metals and radionuclides by earthworms was also assessed, to clarify cause-effect relationships. Earthworms were exposed in situ, to a contaminated soil from the Cunha Baixa uranium mine and to LUFA 2.2 soil (control soil). Organisms were sampled from the assay chambers after 0h, 24h, 48 h, 7 days, 14 days and 56 days of exposure. Higher DNA damage, detected by comet assay and flow cytometry, was recorded in earthworms exposed to the contaminated soil. The measurement of cell frequency, median fluorescence intensity (MFI), DNA content and coelomocytes proliferation, by flow cytometry, revealed changes in earthworms immune system and toxicity to coelomocytes. Earthworm's biomass was significantly decreased and the reproduction was also significantly affected in earthworms exposed to the contaminated soil, as cocoon production was completely inhibited in these organisms. Earthworms also showed bioaccumulation of metals and radionuclides. These results suggest that earthworm's reproduction assay and the determination of genotoxicity and cytotoxicity endpoints are applicable to in situ exposures and may constitute powerful tools for environmental risk assessment of radioactive mining areas.

**MO 202**

**Transcriptional regulation of metallothionein and catalase in Eisenia fetida artificially exposed to cadmium in OECD soils with different concentrations of organic matter**

AR Izquierdo, A Irizar, O Diaz de Cerio, E Bilbao, M Soto, I Cancio, I Marigómez

UPV/EHU, LEIOA, Spain

Exposure of earthworms to metal contaminated soils, results in the regulation of the transcription of a set of genes, which are considered to be molecular biomarkers of exposure to metals. Metallothioneins (MTs), are proteins in charge of sequestering and detoxifying non-essential metals, and regulating concentrations of essential ones, in all animals studied to date. Thus, the transcriptional induction of MTs has become a biomarker commonly used to study the quality of soils. Some metals, such as Cd, also regulate the activity of enzymes such as catalase (CAT), that participate in the antioxidant defense against the oxidative stress generated by the exposure. Traditionally, ecotoxicological assays, both acute exposure and sublethal effect assays, are carried out using standard soils, such as OECD soils (1984), with 10% organic matter (OM) content. But real soils can be very different in their OM content, this modulating the bioavailability of contaminants and their derived biological effects. The present work aimed to analyze the transcriptional regulation of MT and CAT by Q-PCR, in earthworms (*Eisenia fetida*) exposed to Cd in OECD soils with different content in OM. With this purpose, earthworms were exposed to 5 and 25 mg Cd/kg in artificial soils with 6, 10 and 14% OM during 3 days. Moreover, we did analyze the differential regulation of studied genes in different body regions along the postclitellar anteroposterior axis. MT was significantly upregulated in a Cd concentration dependent manner, both in soils with 6 and 10% OM, but not in animals in soils with 14% OM. On the other hand, CAT was only significantly downregulated in earthworms in the spiked soils with 10% OM. No significant differences were observed when comparing transcription levels in the anterior and posterior part of the worm bodies, but in the case of CAT in animals exposed to 5 mg Cd/kg only the anterior part showed a significant downregulation. Therefore, the studied gene transcriptional levels point the need to consider concentrations of organic matter in natural soils when trying to interpret results obtained with biomarkers applied on sentinel earthworms.

Funded: Basque Government (ETORTEK BERRILUR IE09-242, INZITOX UE09+/58 and Grant to Consolidated Research Groups GIC07/26-IT-393-07) and BFA (LURTXIP Project). A.I. is recipient of a pre-doctoral fellowship from the Basque Government.

**Assessment of plant protection products on soil communities under Mediterranean conditions: field evaluations**

PAS Leitão[1], MJ Cerejeira[1], P van den Brink[2], JP Sousa[3]

[1]Instituto Superior de Agronomia, Technical University of Lisbon, LISBOA, Portugal

[2]Alterra and Wageningen University, P. O. box 47, 6700AA, WAGENINGEN, The Netherlands

[3]IMAR-CMA, Department of Life Sciences, University of Coimbra, COIMBRA, Portugal

Complying with the Sixth Community Environment Action Programme an integrated approach to assess the risk (both fate and effect aspects) of plant protection products on soil communities under Mediterranean conditions was put into practice. Our aim was to contribute to increase knowledge about ecological scenarios under Mediterranean conditions where soil characteristics, climatic conditions and biota are different from those under central and northern Europe. The effect assessment component presented here embraced different levels of environmental complexity: (1) a first-tier comprising laboratory single species tests with terrestrial organisms with 3 model pesticides (chlorothalonil, ethoprophos, azoxystrobin) selected based on the result of acceptance in inclusion in Annex I of Directive 91/414/EEC and as being regularly used in Portuguese model crop systems (potato, maize, onion); (2) and a higher tier comprising field testing of indigenous edaphic communities in a selected study-site located in an intensive crop area and with high irrigation needs neighbouring protected wetlands.

This field study comprised a complete crop cycle with multiple pesticide applications and fertilization under realistic conditions. Sampling was done between Mach and October 2010 in several parcels, both in-crop and off-crop. The organisms were collected using several methodologies (embracing soil macro and mesofauna and soil fauna feeding activity), and samplings were undertaken according to pesticide and fertilizer application. The first data on this field evaluation is presented in this panel. The results from this higher tier (reflecting a realist scenario and thus considered as a reference tier defining protection levels for the lower tier) will be compared with those obtained from the lower tier to evaluate its level of protection towards soil organisms. This analysis will contribute to a more realistic pesticide risk assessment considering the different levels of complexity of agricultural ecosystems.

**MO 204**

**Soil respiration under the fungicide Captan and the bactericide Bronopol revealed different stability of fallow and meadow soil microbial communities**

D Chmolowska

Jagiellonian University, KRAKOW, Poland

Due to socio-economical transformations that Poland underwent in the last 20 years, major changes in the land use have taken place in the country. Lowering cost-effectiveness of agricultural production led to a huge increase in the area of abandoned farmlands. Such fallows undergo rapid secondary succession and are examples of unstable ecosystems under changes. The successional changes in plant communities are expected to be reflected in soil microbial communities, offering an interesting system to study stability of communities.

For this reason soil microbial communities from abandoned agricultural lands were compared to communities from rich and well maintained meadows. In this work their resistance and resilience to the bactericide Bronopol and the fungicide Captan was evaluated. Six fallows and six meadows were included in the investigation. Soils were spiked with Captan and Bronopol in laboratory conditions at a rate 5.4 mg a.i. per g dry soil, what corresponds to a concentration approximately 50 times higher than recommended for Captan. Soil respiration rate was measured weekly for six weeks. At the end of the experiment glucose solution was added to soils and active biomass was estimated.

Fallow and meadow soils exhibited opposite reaction to Bronopol in terms of shape and time of changes. The respiration rate of meadow soils increased one day after the amendments and afterwards decreased to levels lower than in respective controls. In contrast, the respiration rate in fallows peaked one week after the treatment and remained elevated in comparison to control throughout whole incubation time.

The shape and timing of response to Captan were similar in meadows and fallows, with an initial increase in the respiration rate followed by a decrease. The communities differed, however, in the intensity of response, which in case of meadows was stronger.

The resilience to the two biocides did not differ significantly, and in 42 days both systems came back to their ground state.

Glucose-active biomass was significantly lower in soils treated with biocides than in respective controls with no difference between the ecosystem types or the pesticides.

In this research the different stability and resistance of soil microbial communities originating from two types of ecosystem was proved. In case of the fungicide only the meadow microbial communities were affected negatively, and in case of the bactericide a significant interaction was found between time and soil origin.

**MO 205**

**Cellulose decomposition in fallow and meadow soils amended with the fungicide Captan and the bactericide Bronopol**

D Chmolowska[1], A Šimonovicová[2], K Kozupa[1]

[1]Jagiellonian University, KRAKOW, Poland

[2]Comenius University, BRATISLAVA, Slovak Republic

Due to socio-economical transformations that Poland underwent in the last 20 years, major changes in the land use have taken place in the country. Lowering cost-effectiveness of agricultural production led to a huge increase in the area of abandoned farmlands. Such fallows undergo rapid secondary succession and are examples of unstable ecosystems under changes. The successional changes in plant communities in such areas are expected to be reflected in soil microbial communities, offering an interesting system to study stability of communities.

For this reason soil microbial communities from abandoned agricultural lands at the initial stage of plant succession were compared to communities from rich and well maintained meadows. In this work their resistance and resilience to the bactericide Bronopol and the fungicide Captan was evaluated. Six fallows and six meadows were used in the investigation. Soils were spiked with Captan and Bronopol in laboratory conditions at a rate 5.4 mg a.i. per g dry soil, what corresponds to a concentration approximately 50 times higher than recommended for Captan. Following the treatment, cellulose decomposition was measured in laboratory conditions. Amended and control soils were put into Petri dishes and three stripes of cellulose filter paper 10 x 50 mm were placed on the moistured soil surface. Vanishing of the cellulose was measured once a week for 8 weeks by the mean of visual measuring via a transparent template. For each soil treatment

study two replicates were used and readings were done by two people independently.
Cellulose was degraded significantly faster in fallow soils than in meadows, especially in the first weeks. Both pesticides decreased the decomposition rate. Captan inhibited the process almost entirely, which conforms with the commonly accepted fact that fungi are the main cellulose decomposers. Nonetheless, in some soils the cellulose decomposed even when amended with the fungicide. Bronopol slowed down cellulose decomposition at first, but with the time the decomposition rate recovered.
The research showed that the degradation of cellulose is carried out faster and more efficiently in fallows. The bactericide Bronopol did not break this relation. Although soils from both ecosystem types were similarly sensitive to the fungicide Captan.

**Does the current EU chronic earthworm risk assessment scheme for plant protection products (PPPs) show an appropriate level of protection?**

A Dinter[1], M Coulson[2], T Leicher[3], MJ Miles[4], C Oberwalder[5], G Weyman[6]
[1]DuPont de Nemours (Deutschland) GmbH, NEU-ISENBURG, Germany
[2]Syngenta Crop Protection AG, BRACKNELL, United Kingdom
[3]Bayer CropScience AG, MONHEIM, Germany
[4]Dow AgroSciences, ABINGDON, United Kingdom
[5]BASF AG, LIMBURGERHOF, Germany
[6]Makhteshim-Agan, BERKSHIRE, United Kingdom

In Annex VI to the EU Directive 91/414/EEC a trigger of ≥ 5, based on the NOEC of the earthworm reproduction study was set as trigger for the long-term risk assessment of PPPs. The ECPA Soil Organisms ad hoc Team analysed the results of earthworm field studies that were triggered due to failure of this chronic earthworm EU Annex VI trigger of 5 and assessed 17 earthworm field studies that were conducted during the last 5 years in line with the technical recommendations for the update of the ISO earthworm field test guideline (ISO 11268-3) (Kula et al. 2006). In all 17 earthworm field studies comprising 10 fungicides, 4 herbicides and 3 insecticides no unacceptable effects on natural earthworm populations were identified at least 12 months after treatment. This is well in line with the data analysis conducted by Heimbach (1998) and Barber et al (1998). Thus it can be concluded that the current chronic EU earthworm risk assessment for PPPs using the NOEC from the chronic laboratory earthworm study and a maximum PECsoil on the basis of 0 to 5 cm soil layer combined with the EU Annex VI trigger value of 5 is conservative and protective. In fact many unnecessary earthworm field studies are being triggered, confirming the safe use of PPPs for earthworms.

**MO 207**

**Reproduction, behaviour and biochemical responses in Enchytraeus albidus (Oligochaeta) exposed to different pesticides**

SC Novais[1], N Gomes[1], AMVM Soares[1], W de Coen[2], MJB Amorim[1]
[1]Cesam & University of Aveiro, AVEIRO, Portugal
[2]University of Antwerp, Department of Biology - E.B.T., GROENENBORGERLAAN 171-U.7., B-2020 ANTW, Belgium

Enchytraeus albidus are typical inhabitants of a wide variety of soil types and fulfil important functions such as improvement of the soil pore structure and, indirectly, the degradation of organic matter. These organisms are very sensitive to chemicals and proved to be suitable for environmental risk assessment through the determination of reproduction and survival endpoints (ISO No. 16387, 2003). The avoidance behaviour is also of great ecological importance and can give useful information about the ability of E. albidus to escape from a contaminated soil. To assess the overall quality of the terrestrial environment and better understand the mechanistic bases of chemical action, increasing emphasis has been given to stress responses at lower levels of biological organization. The antioxidant defenses are among the most used biomarkers due to their crucial role in cell homeostasis preventing DNA damage, enzymatic inactivation and lipid peroxidation. Cholinesterases are also important and commonly used biomarkers, namely acetylcholinesterase involved in neuro-muscular function of organisms.
The main goals of this study were: 1) to investigate the effects of different pesticides on survival, reproduction and behaviour of E. albidus; 2) to assess the oxidative stress effects at concentrations that affected survival and reproduction. Additionally, the effects of exposure time (2, 4, 8, 14 and 21 days) on the biomarker responses were investigated. Survival, reproduction and avoidance behaviour assays were performed according to standard guidelines. The biochemical parameters measured in E. albidus whole body were lipid peroxidation (LPO), glutathione redox status, superoxide dismutase (SOD), catalase (CAT), glutathione reductase (GR), glutathione peroxidase (GPx), glutathione S-transferase (GST) and cholinesterases (ChE).
The results showed effects on survival, reproduction and avoidance behaviour. Reproduction was the most sensitive endpoint. The biochemical responses were affected by the pesticide exposures in the different time points.
This study shows that the determination of effects at different levels of biological organization allow going further on understanding the mechanisms of toxicity that may contribute to mortality and/or reproduction impairment by pesticides.

**MO 208**

**Will juveniles, pre-adults and adults respond in the same way to chemical exposure? The study case of dimethoate.**

GC Ferreira, P Tourinho, MVM Soares, S Loureiro
CESAM & Dep. Biology, University of Aveiro, AVEIRO, Portugal

In a field situation, organisms are not exposed to a stressor under similar age, growth or moulting stage or even in a determined gender ratio.
A high number of studies focus on the effects of a specific stressor in a specific growth stage (adults or juveniles) mainly due to the fact that juveniles are more sensitive then adults, and that effects on adults will always be related to reproduction and the decrease of the population. Pre-adult or juvenile organisms are not so often used in terrestrial ecotoxicological studies and their response can also be very important and crucial for ecosystem dynamics.
Taking in consideration the three growth stages described before (juveniles, pre-adults and adults), and that to our knowledge no data as been yet published regarding these three stages and their inherent physiological processes, we studied the potential recovery process in all growth stages, regardless the lower or higher chronic effect induced by a specific stressor.
The study consisted in a total of five replicates per age range corresponding to a plastic box with 20 isopods during a 7-day exposure period. Organisms belonged to three different stages (juveniles, pre-adults and adults) were exposed to 10 mg dimethoate/kg soil (concentration below EC50).
Biomarkers (e.g. AChE, LPO, GST, CAT, etc.), energy reserves content (lipids, carbohydrates and proteins), energy consumption and cellular energy allocation (CEA) were determined after exposure.
The present work showed that the response in biomarkers is not equal for all age stages and the detoxification processes do not respond or evolve in the same way.

**MO 209**

**The effect of 1,4-dichlorobenzene on soil organisms**

H Motejlová, T Sovová, V Kocí
Institute of chemical technology Prague, PRAGUE, Czech Republic

1,4 - dichlorobenzene is hazardous substance belonging to the group of chlorinated aromatic hydrocarbons which is present in all components of environment. It is a raw material commonly used in industry for example for producing pesticides. Especially the industrial activity, application of sludge on agricultural land or atmospheric deposition are the cause of pollution 1,4-DCB of particular components of environment. Ecotoxicity data for 1,4-DCB for aquatic environment can be found in the literature but there is an absence of information for terrestrial environment. The main aim of this study is to determine sensitivity of soil organisms compared with tested substance 1,4-DCB using a set of contact toxicity tests. The same concentration range of 1,4-DCB 125, 250, 500, 750 a 1000 $mg.kg^{-1}$ was selected for all tests. Toxicity was determined by the help of a set of four terrestrial tests: determination of effects on reproduction and survival of Enchytraeidae (*Enchytraeus crypticus*), further avoidance tests with Enchytraeus crypticus, inhibition of reproduction of Collembola (*Folsomia candida*) and the last one is the determination of effect of pollutants on lettuce seedlings (*Lactuca sativa* L.). This study is in the same time a part of next research which is related to the characterization factors in the methodology CML-IA (CML impact assessment) because 1,4-DCB is one of reference substances used in the methodology CML-IA for LCIA (Life Cycle Impact Assessment) in analysis LCA (Life Cycle Assessment).

**MO 210**

**Effects of petroleum hydrocarbons on photosynthetic plant physiological parameters: Chlorophyll Fluorescence and Stomatal Conductance**

N Alonso-Blázquez, A González, C del Río, MD Fernández
Instituto Nacional de Investigación y Tecnología Agraria y Alimentaria (INIA), MADRID, Spain

Biochemical and physiological changes due to contaminants can be detected earlier than morphological changes. Plant physiological functions such as photosynthesis and stomatal conductance are useful tools to study the effects of environmental stress on plants. Photosynthesis evaluated by the variable chlorophyll a fluorescence and stomatal conductance are considered very sensitive biomarkers when plants have been exposed to pollutants. These functions have been widely applied to study effects caused by water deficit, temperature, nutrient deficiency, etc. Their use in determining effects due to chemicals is more limited and mainly addressed to metals and herbicides.
The purpose of this study was to assess the effects of petroleum hydrocarbons on photosynthesis responses and stomatal conductance. Moreover, their application as non invasive measurement endpoints to assess soil contamination was evaluated. Two hydrocarbon mixtures: diesel fuel and mineral oil, were studied in a dose-response assay with two plant species (Cucumis sativus and Zea mays). The plants were sown on the contaminated soil or germinated in a nursery one week before transplanting to the contaminated soil. The objective was to compare the effects on plants with a fully developed photosynthetic apparatus and plants with a developing photosynthetic apparatus to hydrocarbons stress. In this way, the influence of the hydrocarbon stress on the developing photosynthetic apparatus could be determined. The effects on chlorophyll fluorescence and stomatal conductance were compared with effects on seedling emergence, plant growth and leaf chlorophyll.
The diesel-contaminated soil were more toxic than mineral oil-contaminated soil.
The sown plants showed higher inhibition in all parameters than transplanted plant, indicating the response of the developing photosynthetic apparatus to petroleum hydrocarbon stress. Cucumis sativus had the highest response in all measured parameters with the exception of stomatal conductance, where Zea mays showed the highest inhibition. In general, effects of contaminants were higher on chlorophyll than on PI, a fluorescence parameter that comprises three main energy fluxes in PSII: absorption, trapping and electron transport.
The usefulness of chlorophyll fluorescence and stomatal conductance as endpoints of toxicity will be conditioned by contaminant type, plant specie and the state of plant development.
This work was funded by Madrid Community through EIADES Project.

**MO 211**

**Soil quality assessment using ecotoxicological and enzymatic tests during monitored natural attenuation of hydrocarbon contaminated soils**

LS Sisinno[1], CD Cunha[1], JC Niemeyer[2], SF Paim[3], ACL Rizzo[1], RC Santos[1], AU Soriano[4]
[1]Centre of Mineral Technology, RIO DE JANEIRO, Brazil
[2]University of Coimbra - Department of Zoology - IMAR-CMA, COIMBRA, Portugal
[3]Federal University of Rio de Janeiro - Department of Microbiology, RIO DE JANEIRO, Brazil
[4]Center of Research and Development of PETROBRAS - CENPES, RIO DE JANEIRO, Brazil

Monitored Natural Attenuation (MNA) is one of non destructive techniques that can be applied in cases of hydrocarbon contaminated soils. However, environmental conditions have a great influence on microbial activity and consequently in contaminants bioavailability during the process. The aim of this work was the evaluation of soil quality treated by MNA after a period of 12 months, 15 months and 18 months (T12, T15, and T18) using as biological indicators an ecotoxicological test with a soil organism (collembolan) and an enzymatic test (soil dehydrogenase activity). Soil samples contaminated with crude oil in concentrations of 0.5%, 2.5%, and 5.0% (w/w) were left in the open subject to weather (exposure to sunlight, rainfall, and ambient temperature) in Rio de Janeiro City, Brazil. The ecotoxicological test applied was avoidance behavior with springtails [ISO 17512-2 - Soil quality - Avoidance test for testing the quality of soils and effects of chemicals - Part 2: Test with collembolans (*Folsomia candida*) - draft] that allows a preliminary assessment in a short period of time, with high degree of sensitivity. Adult springtails were exposed simultaneously to the control soil and the test soil. These soils were introduced into each test vessel in opposite sides and after an incubation period of 2 days, the number of springtails was determined in each side of the vessels. The mean number of individuals at the end of the test in the test soil was compared to the mean number of individuals in the control soil using Fisher Test. Control soils were an artificial tropical soil, prepared as ABNT NBR 15537:2007 (Brazilian Standard Rule), and the natural soil without contamination. The enzymatic test was based on the use of Triphenyltetrazolium Chloride (TTC Method). The results showed that samples treated after the period of 12 months were no toxic for the springtail in the avoidance behavior test for all the concentrations, while in T15 and T18 the results for 2.5% and 5.0% concentrations indicated toxicity (avoidance behavior). Simultaneously, it can be noted that in T12 the soil dehydrogenase activity was lower than in 15 and 18 months of treatment. These results may be related to the increase of rainfall in T15 and T18, influencing the bioavailability of the contaminants.

### MO 212

**Comparison of bioassay- and chemical analysis in risk assessment of PAH-contaminated remediated soils**

ME Larsson[1], A Rotander[1], T von Kronhelm[2], B van Bavel[1], M Engwall[1]
[1]MTM Research Center, ÖREBRO, Sweden
[2]SAKAB AB, KUMLA, Sweden

Contaminated sites are a worldwide problem. Many of the sites are polluted with chemicals that are harmful to the environment and humans. In Sweden some of the most contaminated areas are being remediated. Polycyclic aromatic hydrocarbons (PAHs) are common in soil at industrial areas and generic guideline values for soil use after remediation are based on the 16 EPA priority pollutants, which only constitute a small part of the complex cocktail of toxicants in many contaminated areas. The purpose with this study was to elucidate to what extent the actual toxicological risks of soil samples from successful remediation projects could be reflected by these PAHs. In this study we therefore compared chemical analysis (GC-MS) and biological analysis (H4IIE-luc) of a number of remediated PAH-contaminated soil samples. The H4IIE-luc bioassay is an Ah receptor based assay that detects all compounds that activate the Ah-receptor, one mechanism for PAH toxicity. By mass balance analysis i.e. comparison of bioassay derived TEQs with chemical TEQ based on REPs, it is possible to estimate the contribution of instrumentally identified compounds to the observed response in the bioanalysis. Comparison of the results showed that the bioassay-determined toxicity (Bio-TEQ) in the soil samples could not be explained to more than a fraction by chemical analysis of the 16 priority PAHs. This pattern was obvious in all samples but the proportions differed between the soils. Our conclusions are therefore that there is a considerable risk that the current risk assessment method for PAH-contaminated soil in use in Sweden, based on chemical analysis of selected PAHs, is missing toxicologically relevant PAHs and other similar substances. Further chemical identification studies and bioanalytical studies are needed to determine whether these unknown substances pose a risk to humans or the environment. Our results showed the weakness of chemical analysis of a small number of compounds as the basis for classification and risk assessment of remediated soil samples. It is therefore reasonable to include mechanism-specific tests in risk assessment and in the classification of remediated PAH-contaminated soils. This could minimize the risk these soils can pose to humans and the environment and enable greater safety in subsequent reuse of remediated soils.

### MO 213

**Relationships between cyclodextrin, SEG, and solvent extracted petroleum hydrocarbon concentrations and the results of toxicity tests with plant, earthworm and soil arthropod species**

L Stephenson, A Angell, J Shrive, M Olaveson, K Ma
Stantec Consulting Ltd., GUELPH, Canada

Two field-collected soils from Saskatchewan (Canada) were amended with commercially-acquired diesel at concentrations ranging from 100 to 30,000 mg/kg soil dry weight; the test soils were artificially aged and weathered by mechanical mixing twice weekly for three weeks prior to use in toxicity tests with plants and soil invertebrates. At the beginning of the tests, soil subsamples were extracted with cyclodextrin, a solvent mixture of hexane and acetone (1:1 v:v), and an enzyme mixture which simulated the gastrointestinal fluids of earthworms (SEG extraction); the exposure concentrations were measured using GC-FID. Toxicity tests with two species each of plants (*Elymus lanceolatus* - Northern Wheatgrass; *Hordeum vulgare*- Barley) and invertebrates (earthworm - *Eisenia andrei*; springtail - *Folsomia candida)* were conducted to determine the biological responses (survival, emergence, growth or reproduction) to a series of diesel concentrations in soil. Multiple regression procedures were applied to the data for the biological responses (ICps), the physico-chemical characteristics of the soils, and the measured concentrations to determine which of the three different extraction methods predicted (correlation) effects.

### MO 214

**Vicia faba root tip micronucleus test: adaptation of the method to a direct soil exposure**

PM Chenon[1], AS Foltête[2], A Benlembarek[1], M Fidenci[3], M Guiresse[3], S Cotelle[2]
[1]RITTMO Agroenvironnement, COLMAR, France
[2]Laboratoire des Interactions Ecotoxicologie, Biodiversité, Ecosystèmes (LIEBE), METZ, France
[3]ECOLAB Laboratoire d'Ecologie Fonctionnelle et Environnement, TOULOUSE, France

The Vicia faba root tip micronucleus test is one of the most employed plant genotoxicity assays, and has been used on various types of contaminated materials. This test has been standardized by AFNOR, the French member organization of ISO. However, this test is usually performed with a water extraction step but soil genotoxicity assessment would be more relevant when performed directly in the soil itself. In order to harmonize these protocols, an ISO standard for the V. faba micronucleus test in both liquid phase (exposure of plants to the water extract of the soil) and solid phase (direct exposure of plants to the soil) would be very useful. In this context, we compared two exposure durations (48h and 5 days) for the V. faba micronucleus test with two different well-known genotoxicants, maleic hydrazide and copper sulphate. We concluded that these two durations induced equivalent sensitivity: the micronucleus frequency was significantly increased with 5 µmol maleic hydrazide per kg dry soil and with 2 mmol copper sulphate per kg dry soil with both exposure durations. However, exposing roots to soil to be tested during 48h is more practical.
We also tested three different soils: two 'natural soils' (lufa 2.1 and lufa 2.2) and an artificial soil according to ISO11268-1 and ISO 11268-2 with the genotoxicant maleic hydrazide 10 µmol per kg dry soil, plants were exposed for 48h. We observed with the three soils cytotoxic and genotoxic effects, these ones were not different between the soils.
The number of replicates has been also studied: three and five replicates gave the same accuracy of the results. Then, the normalisation is proposed with 3 replicates, decreasing the experimental heaviness.
In the framework of standardisation, some more experiment shall be done for testing the use of organic fertilisers with this method. An international ring test will be organised in 2011 to validate the method.
The authors thank the French Agency for the Environment and Energy Management (ADEME, Angers, France) and Region Lorraine for financial support.

### MO 215

**Automated evaluation of ecotoxicologic test systems by image analysis**

S Kimmel, T Schmidt, JP Magyar, S Höger
Harlan Laboratories Ltd., ITINGEN, Switzerland

Analysis of ecotoxicologic test systems frequently requires the counting of many hundreds of objects on several treatments and replicates. Manual counting of such systems is time consuming, is of limited reproducibility and is difficult to verify and to document. These deficits can be resolved by automated image analysis and particle counting. The ecotoxicology tests which can profit from automated image analysis-based counting include but are not restricted to Collembolan reproduction (OECD 232), Lemna growth inhibition (OECD 221) and honeybee brood studies.
As a first step to establish automated counting of Collembola reproduction studies, optimized computer-assisted digital image acquisition to deliver high resolution images with maximal contrast and minimal reflections was established.
Second, customized macros of the public domain image analysis program ImageJ were created. These macros allow the image analysis and particle counting of any number of images in a folder (batch processing), provide full analysis report of individual images (e.g. non-destructive labelling of individual Collembola, thumbnail collection of all counts, full report of all parameter settings), enable human control and revision if necessary and enable the measurement of additional morphometric parameter (e.g. size or shape).
Third, validation of the automated image analysis-based counting was conducted by comparing it to the manual counting of the same digital images.
This comparison has shown that the automated image analysis delivers comparable results (within the range of variation), but is by far superior with regard to speed, reproducibility, and documentation. Further on sub-lethal endpoints such as size and form of the counted offspring can be taken into consideration.

### MO 216

**The potential use of 5% peat content OECD soil for earthworm reproduction tests**

C Taylor, E Keogh
Covance Laboratories, HARROGATE, United Kingdom

The aim of the work presented is to investigate whether a valid Eisenia fetida (earthworm) reproduction test (OECD guideline 222) can be performed using an OECD test substrate of 5% peat content, as used in other OECD guidelines for soil organisms in the terrestrial environment. The result of a successful test with this peat content would negate the need to divide the NOEC of a test substance by a factor of 2 when calculating the PNEC (Predicted No Effect Concentration) of a compound. To accompany this, a more suitable reference substance should also be ascertained, ideally with a log Kow of >2, i.e. with a higher affinity for organic matter so that it will bind to the peat in substrate thus allowing direct comparison between 5% and 10% peat content.

### MO 217

**Mustard powder and allyl-isothiocyanate (AITC): possible substitutes for formalin as expellants of deep-burrowing earthworms?**

TJ Vollmer, O Klein, S Knaebe
Eurofins Agroscience Services GmbH, NIEFERN-OESCHELBRONN, Germany

Hand-sorting earthworms from a defined soil volume with subsequent extraction of the deep-burrowing earthworms from the soil below the excavated hole is a widely used and well described method for the determination of size and structure of earthworm populations. The extraction is done using a formalin solution, a method recommended in the current guidance document for field trials. However, the use of formalin has its draw-backs, as it is not only harmful to humans but also to soil organisms and plants. Mustard powder and oil of mustard (AITC, Allyl-Isothiocyanate) hold more favourable toxicological and ecotoxicological properties. They have already been tested as earthworm expellants in field experiments with mixed results, but only for direct application onto the soil surface. The aim of this study was compare the efficiency of aqueous solutions of yellow mustard powder (6 g $L^{-1}$), brown mustard powder (6 g $L^{-1}$) and AITC (0.1 g $L^{-1}$) in extracting earthworms from the soil below hand-sorting holes to that of a formalin solution (2 g $L^{-1}$ formaldehyde). The comparison was carried out at five sites with different soil characteristics and cropping history (3 arable with grass-clover, 2 meadows). The sites are located in southern Germany and the sampling took place in autumn 2010. At each site, four replicates (square holes of 0.25 $m^2$, 0.2 m deep) per expellant were sampled.
Yellow mustard powder extracted the largest number of earthworms at one site and formalin at the other four sites, but there was no statistically significant difference in the numbers and biomass of extracted earthworms between formalin, AITC and yellow mustard at four of the five sites. Brown mustard was significantly less effective than formalin and AITC at the same four sites and significantly less effective than yellow mustard at three sites. The results of the study indicate that AITC and yellow mustard powder could be suitable replacements for formalin for the extraction of deep-burrowing earthworms from below hand-sorting holes. However, it seems that soil characteristics and/or environmental conditions during extraction influence the efficacy. Further tests under varying soil and environmental conditions should be carried out to evaluate the influence of these conditions on earthworm extraction.

### MO 218

**Alterations in the endocytotic ability of Eisenia fetida coelomocytes to assess the toxicology profiles of standard soils with different organic matter content and sublethal cadmium concentrations**

MP Rodríguez[1], AR Izquierdo[1], A Irizar[1], I Cancio[1], M Soto[1], I Marigómez[2]
[1]UPV/EHU, LEIOA, Spain
[2]University of the Basque Country, LEIOA-BIZKAIA, Spain

Metals are ubiquitous elements in ecosystems that may cause a great variety of deleterious effects at different levels of biological organization. *Eisenia fetida* earthworms are known as important sentinel species for soil pollution assessment, and their immune system is considered a key compartment to study integrated responses to pollutants since represents a major defense line against them. Coelomocytes, free flowing immune cells of the coelomic cavity, have been given special attention for ecotoxicological effects studies due to their sensibility to toxicants exposure. The aims of the present work are, first to determine the optimal number of individuals to use in a routine protocol for toxicity testing of soil, based on testing of neutral red uptake in coelomocytes extracted from the earthworm *Eisenia fetida* exposed in vivo to Cd. Second, to apply this protocol to determine sublethal response profiles for this species, subjected to exposure in soils artificially contaminated with different concentrations of Cd and different organic matter content (%OM). The experimental design consisted in two phases (based on 3 d exposure experiments). The first phase, which determined the optimal number of individuals, was conducted in OECD artificial soil contaminated with three different concentrations of Cd. The second phase was designed using the optimal number of individuals identified in the first phase, and using OECD soil and modified soil OECD with different %OM (added peat). The optimal sample size was determined to be one pool of 5 specimens. A significant decrease in the endocytotic activity of coelomocytes was detected at decreasing concentrations of OM and increasing concentrations of Cd. Indeed, Cd bioaccumulation also decreased at increasing %OM in soil.
Funded: Basque Government (ETORTEK BERRILUR IE09-242, INZITOX UE09+/58 and

Grant to Consolidated Research Groups, GIC07/26-IT-393-07) and BFA (LURTXIP Project). A.I. is recipient of a pre-doctoral fellowship from the Basque Government.

**Mesocosm soil ecological risk assessment tool for GMO 2nd tier studies**

A D'Annibale[1], K Maraldo[2], T Larsen[3], B Strandberg[1], J Cortet[4], E Vincze[2], P Audisio[5], PH Krogh[1]
[1]NERI (National Environmental Research Institute) - University of Aarhus, SILKEBORG, Denmark
[2]University of Aarhus, AARHUS, Denmark
[3]Christian Albrecht University of Kiel, KIEL, Germany
[4]ENSAIA-INPL/INRA, UMR 1120, VANDOEUVRE-LÈS-NANCY, France
[5]Sapienza Università di Roma, ROME, Italy

Ecological Risk Assessment (ERA) of GMO is basically identical to ERA of chemical substances, when it comes to assessing specific effects of the GMO plant material on the soil ecosystem. The tiered approach always include the option of studying more complex but still realistic ecosystem level effects in 2nd tier caged experimental systems, cf. the new GMO ERA guidance: EFSA Journal 2010; 8(11):1879. We propose to perform a trophic structure analysis, TSA, and include the trophic structure as an ecological endpoint to gain more direct insight into the change in interactions between species, i.e. the food-web structure, instead of relying only on the indirect evidence from population abundances. The approach was applied for effect assessment in the agro-ecosystem where we combined factors of elevated CO2, viz. global climate change, and GMO plant effects. A multi-species (Collembola, Acari and Enchytraeidae) mesocosm factorial experiment was set up in a greenhouse at ambient CO2 and 450 ppm CO2 with a GM barley variety and conventional varieties. The GM barley differed concerning the composition of amino acids in the grain (antisense C-hordein line). The fungicide carbendazim acted as a positive control. After 5 and 11 weeks, data on populations, plants and soil organic matter decomposition were evaluated. Natural abundances of stable isotopes, 13C and 15N, of animals, soil, plants and added organic matter (crushed maize leaves) were used to describe the soil food web structure.

## HM01 - Characterisation and remediation of contaminated soils and sediments

**As transport characterization in the vadose zone of the soil: a combined study between field and laboratory experiments**

J Michel, C Rollin
INERIS, VERNEUIL EN HALATTE, France

Heavy metals are major soil pollutants since a lot of former industrial soils are polluted by these contaminants. In the context of risk assessment of contaminated sites, they are of particular concerns because of their toxicity toward human beings. Nevertheless, the vadose zone of the soil is not taken into consideration in this kind of studies though this is where the pollution enters the soil. That is why mechanisms responsible for trace element release in the unsaturated zone of the soil have to be understood. In addition, tools and methods to measure and put forward interactions between contaminants and the solid matrix have to be provided. Thus the aim of this study was to characterize As transport in soils in the field and to put forward mechanisms responsible for its migration in the unsaturated zone of the soil by setting up an original laboratory experiment.
The study site was an in-service wood preserving facility site, located in the north east of France. A regulatory monitoring of the groundwater quality was initiated by a prefectural order in 1998 and 4 water wells are monitored. Water samples are taken twice a year. Soils were contaminated with Cr, Cu and As and we were mainly interested in As release since it was the only trace element measured in groundwater at a concentration above the EU guidelines for drinking water quality. Soils were sandy clay loam. On site, the mean depth of the water table was 6 m from the ground surface; the water table level variation was about 1 m over a year. Soils were sampled and analyze for physico-chemical characteristics and total As content and were submitted to a sequential extraction. In addition, two columns (30 cm high and 12 cm in diameter) were filled with 2 sub-samples of the As contaminated soil (202 and 253 mg/kg) and As release was studied as it could occur on site. Two main phenomena were simulated during these experiments: rain water infiltration and an increase in the water table level.
Field studies in combination with a statistical analysis showed that As release was highly correlated to the water table level. After the results of the laboratory experiments, it was shown that As concentrations at the outlet of the two columns were constant over time. Given that and the results of the sequential extraction carried out on this soil, As release could mainly occur from the soluble and exchangeable fractions of As. Arsenic transport modeling is in progress in order to confirm this hypothesis.

**Comparative study of chemical species of mercury in contaminated soils from Spanish-colony mining activities in four the Mexican States (Guanajuato, Hidalgo, Queretaro and Zacatecas)**

E Santos-Santos, IG Gavilan-Garcia, AG Gavilan
FACULTAD DE QUIMICA, UNIVERSIDAD NACIONAL AUTONOMA DE MEXICO, MEXICO CITY, Mexico

Amalgamation was heavily used in mining since 1557 in Spanish Colonies in the American Continent. In Mexico and other parts of Latin-America, this process generated mercury containing tailings which were left aside in the mine backyards and with the pass of the years dispersed by rain and wind through vast areas close to different settlements in the Mexican States of Guanajuato, Hidalgo, Queretaro and Zacatecas. Those areas currently represent a potential risk to health and environment since crop farming activities are being developed. The aim of this study was to develop of an integrated, efficient and cost-effective methodology for identifying the mercury species according to their solubility (water-soluble, weak acids, organic acids, and aqua-regia) suitable to characteristic mining contaminated soils of Mexico in order to identify hotspots where remediation or containment activities should be developed. Sites with mining background were selected in the states of Guanajuato (Guanajuato), Hidalgo (Pachuca and Zimapan), Queretaro (Pinal de Amoles and San Joaquin) and Zacatecas (Osiris and La Zacatecana). From the preliminary results of the study, it is estimated that the potential risk is low for the selected sites since mercury is found in stable species (amalgam and sulfide). However, there are some companies that are reprocessing the old tailings to obtain the residual silver left in those materials in Zacatecas and there are mercury extraction activities in Queretaro; this represents a potential risk since these activities might modify the stability of the chemical species of mercury, increasing its solubility. In the case of Hidalgo high concentrations of mercury were found in the nearby of a residential area in the city of Pachuca and ingestion of particles by population is a potential risk.

**MO 225**

**Characterisation of an oil contaminated soil using comprehensive gas chromatography time of flight mass spectrometry (GCxGC-ToF-MS)**

CE West, AG Scarlett, SJ Rowland
University of Plymouth, PLYMOUTH, United Kingdom

Characterisation of the chemical composition of an oil contaminated soil represents a vital step in the development of an effective remediation strategy. Information on the chemical composition of such complex mixtures is used, as part of a risk assessment, to assess the toxicity and subsequently identify the most suitable technology for treatment. Therefore, the quality of the risk assessment and the probability for a successful soil remediation will improve with the level of chemical characterisation. Currently, analyses of these complex samples is conducted using standard protocols based on gas chromatography with flame ionisation detection (GC/FID) or in a few cases gas chromatography with mass spectrometry (GC/MS). A common feature in the GC traces of oil contaminated soil samples, especially when weathered, is the presence of an unresolved complex mixture (UCM), the concentration of which typically far exceeds the concentrations of the limited number of individual priority pollutants which conventional methods can characterise.
In the present study we report the application of comprehensive gas chromatography-time of flight-mass spectrometry (GCxGC-ToF-MS) for the analysis of soil samples taken from a site contaminated by aviation fuel oil. GCxGC-ToF-MS examination of the oil contaminated soil extract provided superior chromatographic separation allowing the characterisation of a wide variety of petroleum-derived hydrocarbons including toxicologically important components such as branched alkylbenzenes (alkyl substituent: C2 to C13) which have previously been reported to affect the health of marine molluscs and crustacea. The chromatographic profile of the contaminated soil sample matched closely to a typical aviation fuel sample analysed under identical experimental conditions, thus allowing the soil extract contaminant source to be distinguished from other common oil contaminants e.g. diesel. The use of GCxGC in the present study provides evidence of improved chromatographic separation and when coupled to ToF-MS yields more reliable peak assignments from mass spectra than previously possible, thereby allowing vastly increased numbers of individual chemical components to be characterised.

**Sunflower roots in combination with indigenous soil micro-organisms for treating hydrocarbon-contaminated soil**

MC Tejeda-Agredano[1], M Grifoll[2], JJ Ortega-Calvo[1], M Cantos[1]
[1]Instituto de Recursos Naturales y Agrobiología de Sevilla (IRNASE), SEVILLE, Spain
[2]Departament de Microbiologia, Universitat de Barcelona, BARCELONA, Spain

Phytoremediation of organic contaminants mainly depends on plant-microbe interactions in the rhizosphere, where, plant roots stimulate microbial populations for enhanced the biodegradation in polluted soil. We conducted a green-house experiment to measure dissipation of polycyclic aromatic hydrocarbons (PAHs) in the rhizosphere of sunflower roots on a creosote-polluted soil (containing 21.75 mg·Kg-1 of 6 PAHs), and an *in vitro* production of root exudates with 50 seeds of sunflower cv. in sterile conditions in an inorganic salts solution used in mineralization experiments (MM; pH=5,7) to study its effect on the biodegradation of phenanthrene and pyrene (present in creosote). In this way, we may separate the chemical impact of the root exudates from any root surface phenomena indicating that sunflower root exudates have the potential to increase the degradation of xenobiotics by the growth of soil microorganisms. In addition, we performed a characterization of these exudates of sunflower to know their total organic carbon (TOC) and composition. It is important to know the organic matter that these exudates provide to the rhizosphere because, their contribution produces an increase in the size of the heterotrophic microbial community and the concentration of PAH-degrading populations, and it is also important to characterize their composition because little is known about the composition of sunflower exudates and their influence on the elimination of PAHs.

**MO 227**

**PCDD/F impact of a secondary aluminum smelter (ALS) on the surrounding environment**

A Colombo, GR Rotella, ML Lodi, SGB Bugatti, EB Benfenati
Istituto di Ricerche Farmacologiche Mario Negri, MILAN, Italy

The aim of the present study was to evaluate the impact of a secondary aluminum smelter (ALS) placed in Piedmont (a region of North West of Italy) and its impact on the surrounding environment. With this purpose we collected ALS emission samples (chimney emissions, fly ash, particulate and wastes), agricultural soils and vegetable and rice samples. PCDD/Fs were measured and expressed as TEQ concentrations according to the international (I-TEF), and World Health Organization toxicity equivalent factors (WHO-TEQ) schemes were calculated. Results obtained indicate a decreasing trend dioxin concentration as the distance from the plant increase, the highest levels were found in soil collected at a distance lower than 500 meter from the ALS, even with values that exceed the reference mean range values for agricultural and natural soils in Piedmont and limit value of 10 pg WHO-TEQ $g^{-1}$ adopted in Italy in soils for green and residential uses. Furthermore PCDD/F concentration decrease from soil though vegetable to rice samples indicating that the contamination is mainly due to atmospheric deposition rather than bioaccumulation in rice plants. To evaluate if the plant investigated might be responsible for PCDD/F contamination in soil collected, Principal Component Analysis (PCA) was performed. Thus source emission and soil samples were included were included. PCA results divide emission samples into two clusters and many of the soil samples collected closest to the plant fall near or inside one of these two clusters.

**MO 228**

**Behaviour and distribution of mercury in soil samples collected from Valdeazogues river (Ciudad Real, Spain)**

RM Millan, MAL Lominchar, MJS Sierra, JRA Rodriguez-Alonso
CIEMAT, MADRID, Spain

The main objective of this study is to determine the behaviour of mercury in the soil of Valdeazogues river (Almadén, Ciudad Real, Spain) by using a six-step sequential extraction procedure developed by CIEMAT (Sánchez et al., 2005). Furthermore, the relationship between the percentage of organic matter in soil and the percentage of mercury associated with the exchangeable and oxidizable fractions is checked.
The results show that total mercury concentrations in soil range from 117 ± 24 to 351 ± 69 mg kg-1. However, the easily available mercury concentration (soluble + exchangeable) is a smaller percentage of total mercury measured in the samples (< 0.16 %). Furthermore, the soluble mer-

cury, in all cases, is less than 0,02 %, so, the leaching process and transport of mercury to surface water and groundwater are very slow. With regard to the distribution of mercury between the different fractions of soil, the metal is associated with more resistant soil fractions, these are: crystalline Fe-Mn oxyhydroxides, organic matter absorbed and the final residue.

### MO 229

**The artificial sweetener saccharin in soils: sources from agriculture and households, degradation, and leaching to groundwater**

IJ Buerge, M Keller, MD Müller, T Poiger
Agroscope Changins-Wädenswil Research Station ACW, WÄDENSWIL, Switzerland

Recent studies have documented the widespread occurrence of artificial sweeteners in the aquatic environment. The sulfoamide saccharin, for example, was detected in most surface waters investigated in Switzerland. Concentrations in lakes correlated with its wastewater burden. Saccharin may also end up in soils through various pathways. Apart from its use as sugar substitute in beverages and food, the sweetener is registered as additive in piglet feed, as it is supposed to facilitate the adaptation to dry feed after the suckling period. Saccharin fed to piglets was largely excreted and, consequently, found in liquid manure at concentrations of 0.3-12 mg/L, where it was stable during two months of storage. Saccharin may thus reach soils in considerable quantities of up to 1000 g per hectare and year with manure application. Furthermore, saccharin is formed in soils by metabolization of certain sulfonylurea herbicides (estimated formation, 1-25 g/ha). Irrigation with wastewater-polluted surface water, fertilization with sewage sludge, and leaks in sewers are further possible sources of saccharin to soils, but these entry pathways were assessed to be of minor importance for saccharin. In batch incubation experiments with six soils, saccharin was degraded with half-lives of 3-12 d. Despite this rapid degradation, saccharin may eventually end up in groundwater, due to high inputs with pig manure and low sorption to soils. Computer simulations predict mean concentrations in soil leachate at 1 m depth of up to 0.3 µg/L. Indeed, saccharin was detected in groundwater at concentrations up to 0.26 µg/L. Under certain conditions, presence of saccharin in groundwater may thus indicate application of pig manure on farmland and leaching to groundwater.

### MO 230

**Uranium accumulation in the plants of the old mine of Sevilha (Central Portugal) - implications for phytoremediation**

PJC Favas[1], JMS Pratas[2], MNV Prasad[3]
[1]University of Trás-os-Montes e Alto Douro, VILA REAL, Portugal
[2]University of Coimbra, COIMBRA, Portugal
[3]University of Hyderabad, HYDERABAD, India

The old uranium (U) mine of Sevilha (Tábua, Central Portugal) is one of several small mines exploited by Portuguese Uranium Company. We decided to evaluate the U accumulation potential of the endemic species. Samples of soil, water and terrestrial and aquatic plants were colleted in the vicinities of the study area. The plant survey did not follow a regular pattern to take into account the dispersion of the species and to sample all the units of the plant community. It was intended to obtain a global view of the response of the vegetation to the accumulation of U. This implied sample collection in the biogeochemical background and within the anomaly. As a result 82 different species we identified and sampled. These species belong to 32 families, five of which are aquatic. All samples were processed at the Chemistry Laboratory of the Earth Sciences Department of University of Coimbra. For determination of mass concentration of U in samples of natural water, soils and plants, it was used the "Fluorat-02-2M"analyzer.
Current U soil contamination on the Sevilha mine ranges from 8 to 560 ppm. In the most abundant families of terrestrial plants, the results show that the Compositae and Ericaceae families have the highest concentrations. For the Composiatae, an average of 4.91 ppm and a maximum of 13.12 ppm was found in Helchrysum stoechas and an average of 4.07 ppm and a maximum of 10.52 ppm was recorded in Hypochaeris radicata. In Erica umbellata an average of 1.70 ppm and a maximum of 7.50 ppm maximum were obtained. Even though the concentrations obtained in this later species are not high it is particularly interesting because it has a high bio-productivity. The water contamination in the vicinities of Sevilha mine results from the natural lixiviation of the wastes used to fill the open pit. Although the U concentrations in waters did not surpass 13 ppb (EPA limit: 30 ppb). Four of the analysed aquatic species proved to be U accumulators. The measured average concentrations were: Riccia fluitans (29.19 ppm), Lemna minor (15.47 ppm), Callitriche stagnallis (9.97 ppm) and Lythrum portula (15.52 ppm). For these species, the observed maximum values were 50.59 ppm, 52.98 ppm, 55.53 ppm and 32.93 ppm, respectively.

### MO 232

**Organochlorines impacts on plant rhizosphere microflora communities**

M Raveton, A San Miguel, RA Geremia, P Ravanel
University of Grenoble, GRENOBLE CEDEX9, France

The aim of our research is to investigate the organochlorines eco-remediation by plant rhizosphere. Such a research requires a multidisciplinary approach integrating microbiology, chemistry and plant physiology studies. Using standard organochlorines (OCs) [lindane, monochloro-, dichloro-, trichloro-benzenes (MCB, DCB, TCB)], rhizosphere microflora associated to Zea mays plants was studied. Samples were collected on control plants and plants exposed to a concentration of 15µg OCs/g dw during 45 days. Using molecular profiling we found that OCs impacted the rizospheric bacterial communities. Bacterial strains from control and treated plants were isolated and cultivated. These strains were characterized by sequencing the 16S RNA gene. A large diversity of bacteria was found in treated and untreated conditions. Strains from some of these genera (Sphingomonas, Pseudomonas, Xanthomonas, Bacillus) are already known to be involved in the detoxification pathways of OCs [1,2,3], while Sphyngobacteria seemed to be sensitive to the presence of OCs mixtures. Current work concerns test on the sensitivity of the isolated bacterial strains to OCs and their capability to mineralize these pollutants.

**Soil management using life cycle impact assessment: environmental state of soil and potential remediation with USEtox model - a decision support**

TD Cruz, J Payet
CYCLECO, AMBÉRIEU-EN-BUGEY, France

Heavy metal and soil contamination are industrially connected. Soil contamination bears itself upon an ecological, dynamic perspective where some weakly known processes are still regarded as a source of uncertainty and variability. Risk assessment and life cycle thinking are welcome tools under this uncertainty. UNEP-SETAC Life Cycle Initiative joint efforts harmonized previous work on toxicological life cycle impact assessment into one single tool - USEtoxTM (Hauschild et al). It is available in a stepwise excel tool to estimate comparative toxic units (CTU) from a unit chemical release. Nevertheless, the factors predicted for inorganic substances are still considered as interim factors and effects in terrestrial organisms are not considered. Despite this, the model can be used to assess the environmental state of a determined region due a specific contamination. Thus, we need to quantify the connection between the emission and the resulting health or ecological effects. Two groups of data are necessary to determine the soil inventory: data regarding the affected soil and data concerning a non-affected soil. Thus, we represent both primary (soil contamination) and secondary (soil remediation) impacts over the life cycle of the site. Using average chemical extraction rates from different technological solutions we can use both impacts (primary and secondary impacts) and assess the potential benefits of each solution (over the life cycle) within different land use. Over the study we compare data from the contaminated site (airborne emission, metal concentration on vegetation, epidemiological data) with predicted results and discuss their variability. Moreover, outcomes from contamination/remediation depend on land use. We analyzed the resulting variability by changing simple soil parameters on the model. Finally, the final technological hierarchy is given by multi-criteria analysis also accounting for social and economic aspects. Developments on risk assessment for human health (Carlon et al.) and biodiversity conservation (Critto et al, E. Boriani et al) are used and applied to a case study where metals as Cadmium, Lead, Zinc are measured in different land uses and inhabitants may be under risk. The large contaminated area, the different pollutants found, the range of stakeholders as well as the expenditure and remediation costs pose a rehabilitation challenge.

**Endosulfan and cypermethrin-induced oxidative stress in plants and their influence on phytoremediation process**

M Mitton[1], M Gonzalez[1], VM Shimabukuro[1], JM Monserrat[2], KSB Miglioranza[1]
[1]Universidad Nacional de Mar de Plata, MAR DEL PLATA, Argentina
[2]Univerisdade Federal do Rio Grande, FURG, Instituto de Ciencias Biológicas, RIO GRANDE, Brazil

Phytoremediation involves the use of vegetation for in situ treatment of contaminated soils, sediments, and water. It is applicable at sites containing organic pollutants where plants can uptake and metabolize them and/or enhance the rhizospheric activity. However, some pollutants are known to enhance Reactive Oxygen Species (ROS) formation and it can affect the efficiency of phytoremediation due to toxic effects. ROS produce oxidative damage to proteins, DNA and lipids. Under optimal growth conditions, ROS are produced at a low level in organelles such as chloroplasts, mitochondria and peroxisomes. However, pesticide uptake can dramatically elevate their rate of production. The aim of this work was to study the oxidative stress in edible plants exposed to soils spiked with a mixture of endosulfan and cypermethrin as a measure of plant tolerance for their use in soil phytoremediation. Lipid peroxidation (malondyaldehide content, MDA) and total antioxidant capacity against peroxyl radicals (ACAP) was measure in leaves and roots of soybean, sunflower, colza and alfalfa plants grown in soil spiked with technical endosulfan (Master® 35%, 5 ppm) and cypermethrin (Goti Glex, cis 40-50, 25%, 0.5 ppm) after 15 and 60 days of exposure. Control plants were grown in the same soil without pesticides. Results showed an increase in the ACAP of roots and leaves at 60 days for most species while MDA levels increase only in leaves. These results can indicate that pesticide uptake and translocation may trigger oxidative damage in leaves. However in older plants, growth leads to higher photosynthesis rate and ROS production that enhance the oxidative damage caused by pesticides. Plants grown in contaminated soils showed lower biomass and growth rate than control plants (clean soils) suggesting pesticide toxicity, and the lower MDA levels would be related to changes in lipid types (ie. lower proportion of unsaturated lipids). The knowledge about the induction of oxidative stress by pesticides is necessary for planning phytoremediation strategies and allows selecting tolerant species according to particular sceneries.

### MO 235

**Effects of apatite mine tailings amendment on toxicity and leaching of shooting derived lead in forest soil**

S Selonen, S Venäläinen, OP Penttinen, H Hartikainen, H Setälä
University of Helsinki, LAHTI, Finland

In Finland, there are roughly 2000-2500 shooting ranges, of which approximately one-third are situating on ground water areas. Dissolution of pellet-derived lead (Pb) into the soil water poses a risk to ecosystems locating in the vicinity of the shooting ranges and, if leached to the groundwater, to human health. Apatite ore beneficiation at the Siilinjärvi carbonatite complex produces mine tailings of versatile chemical and mineralogical properties that may allow the material to act as a sorbent for Pb *in situ*. The aim of the study was to investigate the tailings-induced changes in the mobility and bioavailability of Pb in contaminated shooting range soil and the effects of tailings amendment on soil organisms responsible for decomposition process in the soil. Five test soils of increasing Pb content were collected from a pine forest locating right behind a shotgun shooting range. Soil from an adjacent uncontaminated site served as a control. In the laboratory, half of each soil was amended with the tailings material. The effects of amendment on (i) the toxicity of the soils and (ii) the leaching of Pb, measured using (iia) closed soil extraction and (iib) open lysimeter system, were studied one day after amendment (short-term effects) and after one year of incubation of the soils (long-term effects). (i) Toxicity of the soils was tested using the Collembola reproduction test and the acute toxicity test on earthworms. (iia) In standardized leaching procedure, soils were extracted using 0.001 M $CaCl_2$ solution, and the Pb concentration in the leachates as well as their toxicity to *Vibrio fischeri*, *Lemna minor* and *Daphnia magna* were measured. (iib) In lysimeter assay, water was poured on top of the soil in each lysimeter pot, and Pb concentration of the leachate water collected in the bottom of the pot was analysed. Amending the soil with the tailings reduced instantly the leaching of Pb in a standardized leaching procedure, but increased it in the lysimeter system. The tailings decreased the toxicity and increased soil pH immediately after application. Increased pH is one of the mechanisms through which the tailings amendment can decrease the availability of lead. Further, it is likely that the increased soil pH itself affects the survival and fitness of the organisms. The results of the long-term effects of tailings amendment - yet to be analyzed - will be crucial to reveal the suitability of the tailings to act as a sorbent for lead in contaminated soil.

**MO 236**

**Enhancement of Cd removal efficiency using phosphate-solubilizing bacteria (PSB) in phytoremediation**

S Jeong[1], T Kim[2], K Nam[1], HS Moon[1]
[1]Seoul National University, SEOUL, South-Korea
[2]Haechun Environment Total Solution Co., BORYEONG, South-Korea

Phytoextraction has demonstrated its beneficial use in the removal of heavy metals from polluted soil. Recently, many researches have focused on plant growth promoting rhizobacteria (PGPR) application to enhance metal removal efficiency during phytoremediation. Phosphate solubilizing bacteria (PSB), one type of the PGPR, can solubilize phosphate in soil and provide nutrients for plant growth and increase the bioavailable of metals in soil. This study is conducted to evaluate the effects of the PSB inoculation on removal of Cd from soil in phytoremediation. Pot tests were carried out using artificially contaminated soil with Cd (72.8±2.01 mg/kg). Brassica juncea and Abutilon theophrasti were used and Bacillus megaterium (DSM No. 3228) was used as PSB. The potential of B. megaterium for solubilizing phosphate from tricalcium phosphate (TCP) or soil was tested. While the concentration of phosphorus in the controls was 10.2 and 0.6 mg/L, the concentration of phosphorus in the sample with TCP or soil were 45.5 and 8.2 mg/L, respectively. These indicate that the bacteria have the potential for solubilizing phosphate in soil. Each pot was inoculated with B. megaterium after 4 weeks of growing and re-inoculated at the 6th and 10th weeks. The plants were harvested at the 4th, 6th and 10th weeks. With B. juncea, the Cd accumulation in the roots, stems and leaves was 0.35, 0.39, and 0.09 mg/g of dried plant mass after 4 weeks, respectively. With A. theophrasti, 0.37 and 0.07 mg/g of dried plant was accumulated. When B. megaterium was inoculated, Cd accumulation increased significantly compared to the controls. Interestingly B. juncea mainly accumulated Cd in their roots, whereas A. theophrasti accumulated Cd in leaves. Translocation factor (TF), which is defined as the ratio of metal concentration in shoots to that in roots can be used to evaluate the capacity of plants accumulating heavy metals. With the application of B. megaterium, TF value for A. theophrasti showed a marked increase from 0.19 to 6.68. This indicates that the amount of Cd extracted from soil by roots and translocated into the above-ground regions such as stems, leaves, and flowers was greater for A. theophrasti. The change of metal speciation in soil and the mechanism of heavy metal transport into plants will be also investigated with the PSB application. The findings from this study will enhance the efficiency of phytoremediation using the PSB application of heavy metal-contaminated soil.

**MO 237**

**Root elongation test with Lactuca sativa in assessment of dredged sediment ecotoxicity**

J Vasickova, J Hofman
Masaryk University, Research Centre for Toxic Compounds in the Environment, BRNO, Czech Republic

Large amount of sediments are dredged each year for the maintenance of water bodies and waterways. The disposal of dredged sediments is an important environmental problem. Reusing of this material as a soil improver and application on agriculture land is one of the possible options. Application must be regulated based on sediment contamination or toxicity, because of high levels of contaminants frequently present in sediments. Novel directive for the dredged sediments application on agricultural land was ratified in the Czech Republic in summer 2009. Root elongation test according to ISO 11269-1 is one of the four toxicity tests suggested in the directive. The objective of this study was to evaluate the suitability of the root elongation test with *Lactuca sativa* as a tool for hazard assessment of the dredged sediments. We evaluated 36 sediments samples both from bottom of rivers and ponds and from stockpiles of dredges materials. Contents of heavy metals, PAHs, PCBs and organochlorinated pesticides were analysed in the samples and compared with the limits values suggested in the new directive. Growth of *Lactuca sativa* roots sensitively responded to high content of contaminants (PAHs, heavy metals) in several sediment samples. In some cases, the toxicity was caused by sediment physico-chemical properties.

**MO 238**

**Carbon amendments as a sediment remediation method: ecotoxicological effects in Lumbriculus variegatus**

IE Nybom, JVK Kukkonen, J Akkanen
University of Eastern Finland, JOENSUU, Finland

Light density black carbonaceous particles such as soot, charcoal and activated carbon (AC) have been established to be efficient sorbents for a wide variety of hydrophobic organic compounds (HOCs). Interest has been directed in to use the AC in sediment remediation as a carbon amendment to bind and stabilize contaminants. Despite the promising results from both laboratory and field experiments, some studies indicates that AC addition may not ensure good ecological quality of the sediment but can in fact alter the behavior of organisms. AC addition has been observed to influence among others growth rate, food consumption, lipid content and sediment preference of several organisms. The results of ecological effects of AC addition vary however from no effect to a significant effect even among studies employed with the same organism. The aim of our research was to clarify biological responses in *Lumbriculus variegatus* to AC addition. Within this study coal based AC was used in three different grain sizes and in six concentrations each (percentage / sediment ww). Natural uncontaminated sediment was used in terms to address the attention to the effects of AC additions. A relatively low dose of AC was found to be sufficient to alter food consumption and growth rate of *L. variegatus*. The effective dosage on AC was dependent on a particle size, as the most pronounced effect consequent of smallest sized powdered AC addition with dosage lower than 0,5%. The results of this study indicate that *L. varieatus* is able to detect and avoid AC added sediment by reducing sediment consumption. Interesting question constitutes, whether reduction in HOC bioaccumulation, observed in several studies could in some scale be a consequence of altered behavior of studied organisms. AC addition based dose-response effect was not observed in reproduction in terms of this study. Ecotoxicological effects of AC amendments requires more investigation and finding the mechanism for the effects is especially important. The challenge is to find AC material and dosage that does not have an effect on organisms but despite the fact will be effective enough to bind HOCs and reduce bioaccumulation.

**MO 239**

**Use of toxicity assays for evaluating the effectiveness of groundwater remediation with Fenton's reagent**

KO Kusk[1], L Bennedsen[2], M Christophersen[3], ND Durant[4], TH Jørgensen[5], A Rein[1], K Rügge[6], PL Bjerg[1]

[6]COWI A/S, DK-2800 KGS. LYNGBY, Denmark

A chemical dump site adjacent to the Danish North Sea holds a variety of constituents from pharmaceutical production including sulfonamides, barbiturates, aniline, pyridine, phenols, benzene, toluene, chlorinated solvents, lithium, copper, lead, mercury, etc. An on-going pilot scale project evaluates in situ chemical oxidation (ISCO) using modified Fenton's reagent (H2O2 + chelated Fe2+) as a groundwater remedy. Three injections were performed over a period to test treatment efficacy. Performance monitoring samples were collected from two depths both prior to and during treatment, and analyzed for toxicity and contaminant chemistry.
Organisms exposed to a mixture will react to all contaminants present and, consequently, the toxic effect will represent a sum effect. In contrast, chemical analyses yield information on individual or possibly groups of contaminants but not necessarily all the contaminants. Thus, using a combination of chemical analyses and toxicity assays yields a more robust understanding of the contaminated site and the risk it poses to the environment. Ground water samples were tested via toxicity assay using algae, crustaceans, luminescent bacteria, nitrifying bacteria and yeast (estrogen screening test). Results from the baseline study showed that the two most sensitive species were the marine diatom Skeletonema costatum and the marine copepod Acartia tonsa. It was found necessary to dilute untreated groundwater samples up to 3400 times to reduce the short-term toxicity to the LC10 level. Samples from the upper layer were 2-4 times more toxic than samples from the lower layer. Applying a safety factor of 10 on these results and combined with a dilution model for the recipient indicated that the ecosystem in an area of the North Sea of approximately 1x7 km is affected by groundwater flow from the contaminated site. Chemical analyses showed that PCE and toluene concentrations up to 137 and 60 mg/L, respectively, in the upper layer Total hydrocarbons were up to 94 mg/L. Sulfonamides and barbiturates were found at 600 µg/L and 200-400 µg/L, respectively. After the second treatment with Fenton's reagent the toxicity had increased and now needed 7100 times dilution to reduce toxicity to the LC10 probably due to mobilization of metals. It is concluded that toxicity assay is a useful tool for evaluating samples from contaminated sites and that toxicity assays and chemical analyses supplement and support each other.

**Microbiotests as screening tools to evaluate potential ecotoxicity of freshwater sediments**

KF Burga[1], R Charlatchka[2], JF Férard[1]
[1]LIEBE, METZ, France
[2]Electricité de France (EDF- R&D), CHATOU, France

Different methods have been developed to assess the toxic potential of freshwater sediments. Different test batteries composed of bioassays of different organisms (bacteria, algae, seaweeds, micro-crustaceans, and plants), belonging to different trophic levels have been recommended to discriminate among samples and decrease uncertainty in sediment quality assessment (Griest et al., 1995; Nimmo et al., 1995, Cote et al., 1998a,b). Chial and Persoone (2002) mentioned the importance of carrying out tests not only with porewaters, but also with whole sediments. Several exposure phases, such as pore waters, elutriates, organic extracts and whole sediments have also been tested (Bombardier and Bermingham, 1999). Here, we focused our research on whole sediments testing with different solid and liquid phase microbiotests : Microtox® solid and pseudo liquid phase assays, algal solid phase assay, Luminotox solid phase assay and ostracod assay.
To synthesize ecotoxicity information, sediment ecotoxicity index scores were calculated to categorize sediments in order of their potential ecotoxicity. The index formula with its corresponding units has been formulated such that resulting values generally vary from 0 to +∞. In this study, the index scores varied from 17 to 2105. Samples were categorized as marginal hazard potential, moderated hazard potential and high hazard potential when the toxicity index score was less of 50, 50-500 and more of 500 respectively. Finally, results of ecotoxicity index scores were compared with physico-chemical parameters of sediments
Results showed that sediments MIR, CAT and CMA2 presented a high hazard potential, toxic effects were observed in all microbiotests tested. In contrast Maxe and BB2 samples were classified as marginal hazard potential and they did not present ecotoxic effects in all microbiotests. Concentrations of metals in sediments were correlated with the ecotoxicity index scores (Pearson's product moment correlation coefficient and associated p-value). Results showed a correlation with concentration of metals especially with Cr (0.850*), Co (0.860*), Pb (0.925*) and Ni (0.735*). Our results demonstrate that the biological responses of the battery of microbiotests has a strong correlation with some contaminants present in sediments; these mean that this battery can give information about the potential ecotoxicity of freshwater sediments.

**Addition of reactive media for the geochemical stabilization of mercury in contaminated sediments**

CJ Ptacek, DW Blowes, SD Daugherty, BD Gibson, K Desrochers, MBJ Lindsay, KE Blowes, JD van de Valk
University of Waterloo, WATERLOO, Canada

The presence of elevated concentrations of Hg in sediments can lead to formation of methylmercury (MeHg) and subsequent uptake of MeHg in the food-chain. This study evaluated the effectiveness of a variety of reactive media on the stabilization of Hg in water-saturated sediments collected from two contrasting watersheds. The sediments were co-blended with attapulgite clay (ATP), organically modified clay (OMC), sulfur (S), and zero valent iron (ZVI). Batch-style and saturated column experiments were conducted to evaluate the effectiveness of the reactive media for stabilizing Hg. In the unamended sediments, large differences in Hg release were observed both within and between the study sites (release from 100 ng $L^{-1}$ to > 100 µg $L^{-1}$ Hg). In the amended sediments, the release of Hg was reduced by 50 to >99% relative to unamended sediment. The greatest stabilization was observed for sediment augmented with a combination of OMC+ATP and a combination of S+ZVI. Under low-flow saturated conditions, aqueous concentrations of Hg were maintained in the low ng $L^{-1}$ range for more than 6 months. After a hiatus in flow, concentrations of Hg increased in the unamended sediment and sediment amended with ATP. Increases in Hg concentration were not observed for sediment amended with OMC+ATP and with S+ZVI. Sectioning of the columns and analysis for MeHg indicated minor increases in solid-phase MeHg concentrations in the treatment containing OMC+ATP. Increases in MeHg were not observed for the other treatments. Solid-phase analyses showed large accumulations of FeS in the S+ZVI amendment. Geochemical speciation calculations indicated supersaturated conditions with respect to Hg sulfide phases for all treatments. Elevated populations of Fe(III) reducing bacteria were observed in the unamended sediments and the sediments amended with ATP and ATP+OMC. Suppressed populations of Fe(III) reducing bacteria and slightly increased populations of $SO_4$ reducing bacteria were observed in the S+ZVI column. These results suggest that large decreases in aqueous Hg concentrations can be achieved through the addition of reactive media, and concentrations in the low ng $L^{-1}$ range can be maintained under varying flow conditions.

**Characterization of DDT and Mercury contaminated sediment in Toce River and Lake Maggiore (Pallanza Bay)**

EC Bizzotto, S Ceccon, JM Pekala, FI Colombo
ENVIRON, MILAN, Italy

To evaluate the need for remedial action in Lake Maggiore (North Italy) and in its tributary (Toce River), sediment characterization activities were performed in 2009-2010. Historically, a DDT manufacturing facility was located on the Toce River and discharged industrial wastewaters containing DDx and mercury to the river. DDT production started in the 1940s and ceased in 1996; radiodating analysis showed that the highest DDx concentrations in sediments are related to the 1970s.

To investigate temporal and spatial distribution of DDx and mercury in sediment and their influence on the whole lake ecosystem, with the objectives of evaluating potential ecological risk and assessing the need for sediment remediation, the following activities were performed:

- chemical concentrations were investigated at various depths in 125 sediment cores. To collect high quality sediment chemistry data, a lightweight sediment-water interface gravity corer was used
- a Sediment Profile Imaging (SPI) camera survey was performed throughout Pallanza Bay and mouth of Toce River to investigate benthos-sediment relationships by documenting gradients in sediment grain size, transport patterns, geochemical processes, and benthic community dynamics
- radiodating analyses were undertaken to better understand sediment accumulation rates and to examine historical trends in chemical loading to the bay
- sediment toxicity to invertebrates was studied with several lines of evidence, including site-specific sediment toxicity studies, site-specific invertebrate community analysis, studies relating DDx tissue concentrations with adverse effects on invertebrates and analysis of benchmark and toxicity testing from major DDx and mercury contaminated sites
- the fish community was investigated by analyzing several species, considering tissue concentrations with adverse effects on fish, comparison of water concentrations with benchmark values and performing fitness evaluation
- fish and invertebrate analyses supported estimation of wildlife exposure to evaluate potential ecological risk.

Bathymetric and morphologic surveys were performed and hydrodynamic parameters were measured to implement a sediment transport model, to understand system variability under different hydrological scenarios.

This poster provides a summary of data collection methods used and the results obtained, as well as conclusions made regarding potential ecological risk and the need for remediation in the lake.

**MO 243**

**Evaluation of a conceptual site model for sediment processes and geochemical conditions in a large industrial port facility, Augusta Bay, Sicily, Italy**

E Bizzotto[1], JM Pekala[2], RJ Wenning[2], F Colombo[1], C Jones[3]
[1]ENVIRON Italy Srl, MILANO, Italy
[2]ENVIRON International Corporation, PHOENIX, ARIZONA, United States of America
[3]Sea Engineering, Inc., SANTA CRUZ, CALIFORNIA, United States of America

Studies of sediment quality in the Augusta Bay industrial harbor identified elevated concentrations of mercury and other metals and organic chemicals in bay sediments. Previous studies primarily focused on the nature and extent of total mercury in sediments, after which, a large-scale dredging remedy was proposed. An understanding of physical and chemical processes and ecological conditions in the bay had not been demonstrated to the extent necessary for conducting a competent environmental impact analysis and engineering evaluation of the proposed remedy. While it had been demonstrated that contamination did exist, there was no demonstration of bioavailability of any of the contaminants, no indication of the source of ecotoxicity, and no evidence of impact to the bay ecology. It was unclear which substances in sediment posed ecological or human health risks, if any, and therefore impossible to recommend an appropriate, safe and effective sediment remedy.

To address this deficiency, further study in 2008 focused on understanding hydrodynamic processes and the geochemical and ecological conditions in the harbor, and the factors that most influence those conditions. First, a conceptual site model was developed to guide the work and establish a foundation to understand how mercury and other chemicals in the sediment enter the aquatic environment, how they are transported within the bay and deposited in sediment, and where routes of exposure to aquatic life and humans might occur. Hydrodynamic monitoring, sediment transport analysis, and bathymetric and sediment profile imaging surveys were performed in representative regions of the industrial harbor. Sediment, surface water and biota sampling, and ecotoxicity testing and ecological risk assessment were conducted at four stations representing different contaminant distributions, ship traffic activities, and hydrodynamic conditions.

Based on this work, it is apparent that mercury in Augusta Bay does not pose a significant threat to the environment and sediment-associated mercury is tightly bound to the sediment, poses no to low toxicity to benthic organisms, and is largely not bioavailable to aquatic fauna. Furthermore, commercial shipping activities in the harbor do not significantly alter mercury conditions in the bay or create new or greater ecological risks. The proposed large-scale dredging remedy for Augusta Bay is unwarranted, and if implemented, would destroy a complex functioning ecosystem.

**MO 244**

**On the use of ELISA commercial test kits for PCB screening in sediments: practical implications**

J Castro-Jiménez[1], C Gonzalez[2], C Blachere-Lopez[2], I Bazin[2], M Avezac[2], G Junqua[2]
[1]Ecole des Mines d'Alés, ALES, France
[2]Ecole des Mines d'Alés, ALES, France

Polychlorinated biphenyls (PCBs) are a family of persistent organic pollutants (POPs) of anthropogenic origin constituted by 209 congeners. PCBs bioaccumulate and have been identified as toxic compounds producing a wide spectrum of adverse health effects in biota and humans. Sediments constitute reservoirs of PCB which may be eventually buried together with particles but also remobilized by the effects of sediment resuspension and mixing by benthic organisms (i.e. bioturbation). Sediment is therefore a key compartment in the study of the quality status of water bodies. PCBs have been proposed for the inclusion into the European Water Framework Directive (WFD) priority list, currently under revision. Moreover, the management of dredged sediments requires useful screening and monitoring tools in order to assess contamination levels prior action decision (e.g. immersion, terrestrial treatment, storage, or valorisation). Various screening methods have been employed for PCB determination in different environmental matrixes in the last decades, immunoassays being one of the most employed.

A performance comparison study between a classical reference method for PCB analysis in sediments and a commercial ELISA test kit is presented. A number of sediments covering a wide pollution range (from clean to polluted areas) have been analysed by both a reference and ELISA methods. The reference method was based on a 24h Soxhlet extraction of sediments followed by gas chromatography-mass spectrometry (GC/MS) analysis. A selected immunoassay commercial test kit was employed for the ELISA determination. Briefly, the sediments were extracted by manual shaking during 1 min and ELISA response was measured by spectrophotometric detection. Preliminary results showed a good correlation between the two methods when identifying the pollution gradient but not in terms of absolute concentrations. ELISA provided a total PCB concentration as Aroclor equivalents whreas GC/MS analysis provided the PCB total concentration as 6 indicator PCB (CB-28, 52, 101, 138, 153, 180) in addition to single congener values. Discussion on the most suitable ELISA applications (e.g. monitoring contaminated sites versus EQS compliance checking) and on the adequacy of ELISA for PCB determination in sediments under the current environmental pollution scenario and the new European regulation framework is also presented.

**MO 245**

**Metal concentration profiles in sediment cores of Guanabara Bay: geochronological evolution**

M Maniero[1], M Bonardi[2], A Giacometti[3], S Lombardo[1], A Cecchin[1], L Da Ponte[1], G Perin[4]
[1]IDEAS Centre - University of Venice, VENICE, Italy
[2]ISMAR - CNR Venice, VENICE, Italy
[3]Environmental Science Dept - University of Venice, VENICE, Italy
[4]IDEAS Centre - University of Venice - Archives of Ecological/Human Toxicology, VENICE, Italy

The present research has been pursued in the frame of TAGUBAR Project (Tangential Guanabara Bay Aeration and Recovery, 2002/2007) - Cooperazione Italiana allo Sviluppo - Ministry for Foreign Affairs of Italy. The main target of the TAGUBAR Project was to transfer technologies for the remediation of the Bay of Guanabara (Rio de Janeiro, Brazil).

Guanabara Bay is one of the largest coastal Bays in Brazil, it measures 31 Km from south to north and has a surface area of about 400 km2 of estuarine waters. It is an eutrophic, pulluted system, impacted by largely untreated domestic runoff from the eight million inhabitants of its basin. Because the Bay is situated in a highly populated and urbanized area, it is subjected to chemical contamination from a variety of sources and pathways. Particularly evident in this area is the heavy metal pollution of industrial and sewage. In effect the immediate area surrounding the estuary is highly industrialized and includes petroleum refineries and chemical manufacturers, so the Bay is subject to organic and inorganic chemicals contamination.

This study, conducted in 2005, focused on the distribution analysis of the main heavy metals, of some metalloids and some alkaline earth metals in order to define the possible geochronological evolution in sediments of the Bay. Special enphasys is been done to the speciation of metals in the sediments.

The study of the general distribution of the contamination was conducted to implement strategies for environmental recovery by MODUS System, that is a special mobile equipment for aeration, pollutant stripping and oxidation to be used in shallow or deep water. In Tagubar Project has been discovered that polluted sediments, aerated with mechanical dredging and mixing, can release a very high amount of pollutants, expecially toxic methals.

The results of the geochronological study on the distribution of the elements tested, in some cases showed a clear change in concentration with depth but in general there has been a degree of uniformity in the distribution, probably caused by bioturbation.

**MO 246**

**Regression model of arsenic distribution in water/sediment system of Sevojno**

JS Kiurski[1], SM Aksentijevic[2], MB Vojinovic Miloradov[1], MT Vucinic Vasic[1]
[1]Faculty of Technical Sciences, NOVI SAD, Serbia
[2]Business Technical College, UZICE, Serbia

This paper reports the results on total arsenic concentration analyzed in water and sediments collected in 2009 spring/summer seasons. Water and sediment samples were analyzed for total arsenic content by hydride generation using ICP device (ICAP Thermo 6500 Duo). Study has been focused on the Djetinja river basin of the area of Western Serbia, near Sevojno. Traditionally the Djetinja river and Dragića spring (Sevojno, Serbia) receive pollution from two different sources, in the upper section of the Dragića stream from a primary metal manufacturing sector, Copper Mill Sevojno and, in its lower section, in the Djetinja river, from untreated urban wastes and intensive agricultural activities. The concentrations of arsenic in water and sediment samples taken in spring were higher than in summer. Measured concentrations of arsenic in water of Dragića streams and Djetinja river downstream does not exceed the maximum allowable concentration according to the Regulations on permitted amounts of hazardous and harmful substances in soil and irrigation water in Serbia.

Adsorption of arsenic was studied using equilibrium distribution coefficient as a function of the concentration of arsenic in water and sediment. Regression analysis provided a quantitative agreement of two variables. Pre-defined (based on theoretical knowledge) to be an independent variable - concentration of arsenic in waste water, and the dependent variable - the concentration of arsenic in the sediment. Distribution of arsenic between the water and sediment showed agreement in use of Freundlich's adsorption isotherm with obtained polynomial dependence:

Spring: y = - 0.0145x2 + 0.0327x - 0.0093

Summer: y = 10-3 (-0.8259 x2 + 0.6878 x + 0.1421)

Keywords: Arsen, water, sediment, adsorption

Acknowledgement. The authors acknowledge the financial support of the Ministry of Science and Technological Development of the Republic of Serbia, within the Project No. 34014.

**Cd2+ and Zn2+ sorption on hydroxyapatite in the presence of EDTA in aqueous solution in equilibrium state**

K Viipsi, K Tõnsuaadu
Tallinn University of Technology, TALLINN, Estonia

Contaminated soil and water presents an unacceptable risk to human and ecological health and must be remediated. The removal of heavy metals from natural waters and soils needs an special attention because their variety of toxic effects. Among different treatments the adsorption technology is attractive due to its efficiency, economy and simple operation. Hydroxyapatite (HAP-$Ca_{10}(PO_4)_6(OH)_2$) is approved and recommended as a effective metal ions binding material.

The binding process on HAP is controlled by number of factors including pH, contact time, type of metal ions in a solution, HAP physico-chemical properties, ect. The fixation of metal ion on HAP surface may take place through one or more simultaneous mechanisms of: ion exchange, surface complexation, dissolution of HAP to form new metal phosphates, and substitution of $Ca^{2+}$ ions in HAP by other metal ions during recrystallization. In soils and natural waters metal ions complexation by organic ligands and competing sorbates must be considered as well. Altough the sorption of heavy metals on HAP has been extensively studied, the dominating mechanism of complexation in the presence of chelating agents is under discussion.
The removal of $Cd^{2+}$ and $Zn^{2+}$ from aqueous solutions by hyrdoxyapatite was investigated with and without EDTA being present. Batch experiments were carried out using synthetic hydroxyapatite with Ca/P 1.60 and a specific surface area of 40.2 $m^2/g$ in the pH range 4 to 9 (25 °C; 0.1 M $KNO_3$). The initial concentrations of $Cd^{2+}$, $Zn^{2+}$ and of EDTA were 0.002 M. The solid-solution ratio was 2 g/L.
The amount of $Cd^{2+}$ and $Zn^{2+}$ removed from the solution increased with increasing pH, reaching ≈ 90 % at pH 9. The presence of EDTA reduced the HAP removal capacity to 13 % due to the formation of $[CdEDTA]^{2-}$ and $[ZnEDTA]^{2-}$ in solution. In a binary solution (Cd+Zn) the competition of metals reduced individual sorption capacity 10-15 % compared with the single component solutions but the total adsorption maximum was approximately constant (0.8 ± 0.1 mM/g). In a Cd-Zn-EDTA-solution the $Cd^{2+}$ sorption was reduced but the sorbed amount of $Zn^{2+}$ did not change remarkably. In any case the sorbed amount of $Zn^{2+}$ was higher compared with $Cd^{2+}$ and was less affected by solution composition. The solubility of HAP increases in the presence of EDTA at pH values above 6, mainly due to the formation of $[CaEDTA]^{2-}$. The surface composition of solid phases was analysed by X-Ray Photoelectron Spectroscopy (XPS).

**Effect of farm management practices on concentrations of halogenated pesticides in New Zealand streams**

P Shahpoury Bahry, KJ Hageman, C Matthaei, F Magbanua
UNIVERSITY OF OTAGO, DUNEDIN, New Zealand

Halogenated pesticides, especially organochlorine pesticides (OCPs), have raised global concern due to their long persistence, low biodegradability, wide distribution in the environment, and chronic adverse effects on wildlife and humans. Because of their high lipophilicity, the bioaccumulation of small fractions of halogenated pesticides can pose potential hazards in the long term. In New Zealand, pesticides have brought considerable financial benefit and no other method of weed and pest management has been as cost-effective. However, financial benefits of using pesticides are often outweighed by negative environmental and health effects. Most OCPs are banned in New Zealand; nevertheless, their persistence means that residues continue to be detected in sediments and other environmental matrices. A number of studies have been published that compare the environmental impacts of different farm management systems. However, to the best of our knowledge, no studies have compared the concentrations of pesticides in stream sediments from conventional, integrated, and organic farms. Hence, the present study aims to determine if different farm management programs affect pesticides concentrations in streams that pass through farms.
The sediment samples being used in this study were collected from farms at five locations on the South Island, New Zealand. The samples were mixed with diatomaceous earth (DE) and then extracted with n-hexane-acetone (1:1 v/v) using accelerated solvent extraction. The extraction cells were loaded with additional DE and Florisil to remove excess moisture and macromolecules, respectively. The final extracts were analyzed for dieldrin, endrin, endrin aldehyde, α-HCH, γ-HCH, trans-chlordane, cis-chlordane, trans-nanochlor, cis-nanochlor, endosulfan I, endosulfan II, endosulfan sulfate, and chlorpyrifos using GC-ECNI/MS. The data was analyzed using SPSS software. The results indicated that the concentrations of dieldrin, endrin+endrin-aldehyde, γ-HCH, and sum of endosulfans were higher in the streams passing through conventional farms compared to integrated and organic farms. Interestingly, the concentration of α-HCH was higher in streams passing through organic farms compared to integrated farms and no significant relationships were found for chlorpyrifos or the sum of chlordanes.

**Characterization of heavy metal contamination of sediments from Douro River basin, Porto, Portugal**

CMCM Couto[1], MJ Rocha[2], F Figueiredo[3], AA Almeida[4]
[1]Requimte,CICS/ISCS, PORTO, Portugal
[2]CIIMAR, CICS/ISCS, PORTO, Portugal
[3]CIIMAR, PORTO, Portugal
[4]2REQUIMTE, Department of Chemical Sciences, Faculty of Pharmacy (U P), PORTO, Portugal

Douro River is the second most important river in Portugal, travelling a total of ca. 900 km until the Atlantic Ocean, approximately 200 km being in the Portuguese territory. Its estuary is located between the cities of Porto (north side) and Vila Nova de Gaia (south side), in Northern Portugal. This area, besides being highly industrialized is also densely populated, and Douro River estuary receives large amounts of untreated sewages as well as continuous discharges of a total of eight wastewater treatment plants. Therefore, the occurrence of significant metal contamination in this area, particularly of sediments, could be expected. Sediments act as important reservoir of many hazardous chemicals, including heavy metals, which make them a secondary source of pollution. This is particularly important when sediments are eroded and transported further downstream (due to flood and resuspension processes). Along the course of the river to the sea, transportation, dilution and redistribution of sediment-associated metals occurs, and this may have an important impact on the chemical and ecological quality status of the estuaries. In order to assess the metal contamination of Douro River basin sediments, samples were collected during 11 campaigns from March 2009 to July 2010 on 6 different sampling sites along the estuary, at both margins. The 66 samples collected were preliminarily evaluated regarding humidity and granulometry. The fine fraction (< 63 μm), as well as a certified reference material (CRM) of estuarine sediment, were then submitted to a microwave-assisted acid digestion (ca. 0.5 g of dry sediment were digested in high-pressure Teflon vessels with 6 ml of suprapure concentrated nitric acid) and the metal content in the obtained solutions were determined by ICP-MS. Preliminary results show Ni, Cu and Pb levels around 50 μg/g, suggesting that the Douro River basin is significantly contaminated by these heavy metals.

**Evaluation of DDx degradation in Sediments of Lago Maggiore (Pallanza Bay): a case study of historical contamination**

S Ceccon
ENVIRON Italy s.r.l., MILANO, Italy

As part of a series of sediment characterization investigations performed in 2009-2010 in the Lago Maggiore (North Italy), radiodating analyses (210Pb and 137Cs) were undertaken in 9 sediment cores to better understand the sediment accumulation rates in the Pallanza Bay (Lago Maggiore) and to examine historical trends in chemical loading of DDx to sediment. Historically, a DDT manufacturing facility was located on the Fiume Toce (that inflows into Pallanza Bay) and discharged industrial wastewaters containing DDx to the river.
In details, radiodating analyses (137Cs, 210Pb) were performed on sediment cores from 9 stations, chosen to span a range of likely sediment accumulation rates. For each station, the sediment accumulation rate was determined based on the activity of 137Cs and 210Pb in 2-4 cm depth increments of each core. Cores recovered for assessment of sediment accumulation rates were also analyzed for DDT isomers and metabolites.
In parallel, sediment chemistry was investigated collecting and analyzing DDT isomers and metabolites (but not investigating isotopes) at various depth in about 80 sediment cores collected throughout the bay.
For both radiodating and chemical analysis, coring relied on a lightweight sediment-water interface gravity corer, to collect undisturbed cores and high quality data.
The assessment of linked geochronology (and their extrapolation to the whole bay) and chemical data improves the comprehension of degradation and DDT fate inside the bay, together with the understanding of sedimentation behavior and historical trends in chemical loading to the bay.
Results show that concentrations of DDx have overall declined significantly relative to both the highest measured concentrations of each analyte at depth, as well as relative to concentrations measured contemporaneous with the 1986 peak in 137Cs activity. For DDT, the most significantly elevated DDT concentrations occurred in the mid-1960s; DDT degradation to DDD or, in minor part, DDE, appears correlated to sedimentation rates in the different location of the bay. This poster presents methods and results with major focus on the ratio DDT/DDx in sediments and considerations about degradation and DDx environmental fate.

**Application of NEBA and sustainability analysis to evaluate sediment management options for ports and harbors**

J Wenning[1], G Reub[1], G Greene[1], S Deacon[2], J Pekala[1]
[1]ENVIRON, EMERYVILLE, United States of America
[2]ENVIRON UK, BATH, United Kingdom

Sustainable sediment management is a comprehensive approach for addressing the long-term management and conservation of clean and polluted sediments. The goal is to maintain current and future services, including human use and ecosystem-based, while balancing the broader environmental, economic, and societal concerns. Typically, sediments are managed on a project-by-project basis without the benefit of a comprehensive, sustainable strategy to reduce costs and improve environmental benefits. Net environmental benefit analysis (NEBA) is one tool increasingly used to forecast different sediment management and remediation decisions. NEBA, incorporating a set of specific quantified ecosystem service metrics, is a framework that provides a scientific basis for balancing the investment costs and labor with the environmental and societal benefits imagined during decision-making. A NEBA identifies the "breakpoints"where costs become disproportionate to the benefits gained. By doing so, sustainable sediment management activities can be identified that minimize impacts on ecological and human use services and maximize value to the public. This presentation presents two case studies demonstrating the use of NEBA and different sustainability evaluation tools to examine the environmental, economic, and social benefits and costs of different sediment management alternatives for addressing PAH and metal-contaminated sediments in a coastal river that has been subject to decades of industrial pollution and storm water discharges. The presentation illustrates the concepts of air, carbon, ecological, energy, and water footprinting and the tools used to identify the tradeoffs between different management options and select the best practical option. Applied appropriately, and with careful consideration of uncertainties, tools such as NEBA and sustainability assessment frameworks are useful to balancing the disparate environmental risks, project costs, economic benefits, and ecological impacts typically involved in the evaluation of port and harbor projects.

## LC01 - Developments in Life Cycle Impact Assessment (LCIA)

**MO 254**

**Are chemical scores better assessed using USEtoxTM or the classical less sophisticated CDV from the EU Ecolabel?**

EG Saouter, LD Steiner, CF Perazzolo
Science & Environnement, GENEVA, Switzerland

USEtoxTM, a multimedia fate modelling, proposes new characterisation factors (CF) for human toxic impact and freshwater ecotoxic impacts to be used in product LCA. Calculated on more than 3000 cghemicals, these CFs constitute a new ranking of chemicals based on their hazard proprieties. USEtoxTM is now also consired by the French consumer product carbone footprint information scheme (under development) to be the basis for the calculation of two additional criteria: human and eco toxicity. Nowadays, Life Cycle Assessment and the EU Ecolabel are the two tools used to identify on the market environmentally friendly products, but do they provide the same answer? Both tools also provide a ranking of chemicals based on their hazard properties, but are the top 10-20 most important toxics identified by these two tools the same? Is there a risk that consumer products get the wrong label?
The comparison exercise between the EU Ecolabelling and the USEtoxTM ranking score have demonstrated that both models identify the same five chemicals of highest concern for the environment and that there is an overall 'ok' agreement between the two models ranking scores. The difference between the two models can probably be explained by differences in the degradation or ecotoxicity data. By using similar fate and effect data in both systems, it is likely that the correlation will become stronger. From a product labelling perspective though, one could conclude that using a simple model as the CDV approach is probably good enough and certainly less subject to variability in the results. The CDV requiring only two parameters while USEtoxTM more than 15, without mentioning the complexity in calculating score.
In any case, if both system are used for product comparison and/or labelling, a list of agreed and peer-review CF must be published to be used by all practionners to avoid that ranking of chemicals or product changes due to a change in the data use for the assessment.

**MO 255**

**Critical review of USEtoxTM and comparison of chemical ranking scores with the EU Eco-**

**label and the EUSES model**
LD Steiner, CF Perazollo, EG Saouter
Science & Environment, GENÈVE, Switzerland
In the last years, the concern for the ecological impact of chemicals in the environment has largely increased and with it the development of tools to assess the risk/hazard of chemicals. Nowadays, Life Cycle Assessment (LCA) appears as a new tool to address this issue, creating a debate with the Risk Assessment (RA) community. In may 2010, after several years of intense work and many workshops held with LCA and RA experts, the consensus model USEtoxTM was officially launched and promoted as a tool for policy makers and regulators.
There might be however a risk of confusion among decision makers and regulators about what USEtoxTM can really do. This confusion comes from the fact that USEtoxTM uses the same wording as RA, suggesting USEtoxTM looks at the risk assessment of chemicals, whereas it rather looks at the hazard associated with chemicals. Can however the same conclusions be drawn from LCA and RA model predictions? Nowadays, Life Cycle Assessment, the EU Ecolabel and the RA based EUSES model are the three tools used to identify environmentally friendly products on the market. But do they provide the same answers? Those tools also provide a ranking of chemicals based on their hazard properties, but are the same top 10-20 most important toxics identified by these three tools? Is there a risk that consumer products get the wrong label?
To attempt to answer those questions, first a critical review of the USEtoxTM model has been carried out. Moreover, the ecotoxicological impact risk of 69 chemicals have been assessed using those 3 different methods: USEtoxTM, the EU Ecolabel and EUSES. These three have very different ranking methods covering complex life cycle assessment approach, simple critical dilution volume approach and classical risk assessment approach, the two last ones being methods already extensively validated.
Preliminary results of chemical ranking using the USEtoxTM and the EU Ecolabel indicate that, despite showing similar trends, the two models agree on the ranking of the five first chemicals only. The large uncertainty associated with complex modelling and the quality of the initial ecotoxicological data, seems to be partly responsible for the observed discrepancies. The large difference in risk/impact assessment observed for a few chemicals have been further investigated to better understand what causes two models with the same objective to have very different prediction, as this could lead to very different decision my policy makers.

**MO 256**
**Normalization references for USEtoxTM-based toxic impact categories: North American and European economic systems**
A Laurent[1], A Lautier[2], RK Rosenbaum[1], SI Olsen[1], MZ Hauschild[1]
[1]Technical University of Denmark, KGS. LYNGBY, Denmark
[2]CIRAIG, Ecole Polytechnique de Montreal, Department of Chemical Engineering, MONTREAL, Canada
As an optional step of the life cycle impact assessment (LCIA) phase in the ISO standards, normalization aims to express the magnitude of the impacts by comparing the characterized results against a common reference situation - the normalization references. In this study, we used inventories of two economic regions, North America and Europe, to calculate normalization references for the three currently-modelled USEtox™-based impact categories, i.e. freshwater ecotoxicity, human toxicity, divided into cancer effects and non-cancer effects. Base years for the references are 2004 for Europe and 2006 for North America. The normalization references have been calculated using recommended factors as well as with interim factors, as needed. It is found that, in spite of different inventory assumptions, the normalization references fall within the same order of magnitude for both North America and Europe. By analysing the most contributing substances, metals turn out to dominate the impacts in both regions. This may be explained by the interim status of the characterization factors (CFs) for metals, which might be overestimated in the current model. Part of the explanation may also lie in the incomplete coverage of organics in both the inventory and the CF databases. With respect to the intended global character of the USEtox™ model, different approaches to determine normalization references of other economic systems (e.g. Asia or world) are discussed in relation to these findings. Overall, we thus recommend the use of the provided set of normalization references for USEtox™, but we also advocate 1) to perform an update as soon as a more comprehensive inventory can be obtained and as soon as characterization factors for metals are revised; 2) to consider extension to other economic systems in order to allow normalization in USEtox™ to be used on a global scale.

**MO 257**
**Spatial differentiation of chemicals in Life Cycle Impact Assessment for ecotoxicity and human toxicity**
S Sala[1], D Marinov[1], A Kounina[2], S Humbert[2], M Margni[2], D Pennington[1]
[1]Joint Research Center European Commission, ISPRA (VA), Italy
[2]Quantis, LAUSANNE, Switzerland
The ability to consider influence of regionalization is recognized as one of the challenge in order to increase relevance of human toxicity and ecotoxicity in life cycle assessment.
In recent years, several spatially distributed fate and transport models of chemicals, i.e. models allowing spatially explicit representations of contaminants from a given spatial distribution of sources were developed.
A key issue to be addressed in the development of the life cycle impact assessment methods and corresponding characterisation factors is the level of spatial detail required in the life cycle impact assessment and the related uncertainties assessment. A cross comparison among several models were performed to determine conditions which warrant spatial resolution for characterisation factors concerning ecotoxicity and human toxicity.
A set of organic chemicals representing large range of substances with different physical chemical properties is used in the evaluation under different emissions scenarios, such as multiple source vs. point source emissions.
Three models (Mappe, Impact world, Usetox) are used to assess fate of chemicals, from the local to the global scale. Global default values of characterisation factors derived from Usetox are compared with the results of Impact world and Mappe to highlight the relevant drivers of impacts and the main constraints in calculating fully spatial resolved characterisation factors at fine resolution.
The results will help practitioners to identify situations for which spatial differentiation in the life cycle impact assessment of toxic chemicals should be considered relevant as well as how to create consistency between inventory and impact assessment regarding regionalization.

**MO 258**
**Interspecies correlation estimates for ecotoxic effects in Life Cycle Impact Assessment**
L Golsteijn, R Zelm, van, AJ Hendriks, MAJ Huijbregts
Radboud University, NIJMEGEN, The Netherlands
Ecotoxicity is often excluded as impact category in Life Cycle Assessments (LCAs), because information is lacking on the fate and effects of many chemicals. This study uses Interspecies Correlation Estimation (ICE) statistical models to enhance the effect dataset to be applied in Life Cycle Impact Assessment (LCIAs). Next to laboratory tests and QSAR-estimations, ICE models have been developed as an additional approach to estimate the toxicity of chemicals to both aquatic organisms and terrestrial wildlife. The acute toxicity value of one species (i.e. the surrogate species) is used to produce correlation toxicity values for multiple species. In this study, we used ICE to estimate hazardous environmental concentrations for 50% of aquatic species, and hazardous doses for 50% of wildlife species. The data were subsequently applied to derive Effect Factors (EFs) for LCIA. As the introduction of estimated data brings additional uncertainty in the input data, the uncertainty in EFs based on ICE needs to be weighted against the uncertainty in EFs based on a low number of experimental data only. The poster shows the EFs based on ICE model estimates, together with their uncertainty ranges. It also compares EFs based on ICE and EFs based on small experimental datasets.

**MO 259**
**Case study to evaluate USEtox and Critical Dilution Volume (CDV) as methods for assessing the ecotoxicity impact of laundry products**
I Muñoz[1], H Franceschini[1], G Vanhoof[2], D Schowanek[2]
[1]Unilever, SHARNBROOK, United Kingdom
[2]Procter & Gamble, BRUSSELS, Belgium
There is increasing interest in the assessment and comparison of the environmental impacts of products. Schemes such as Grenelle de l'Environnement, currently under development in France, aim to assess and communicate the impacts of consumer products for a few selected impact categories, including freshwater ecotoxicity. This poster presents the results of a case study to compare USEtox and Critical Dilution Volume (Eco-labelling) for assessing the ecotoxicity impacts of laundry products. The scope of the study focused on the end-of-life stage, i.e. when the products are discharged after use into the wastewater system, whereas the 'cradle to factory gate' impacts have been excluded. The poster presents the results of the case studies and discusses the application and limitations of each method within the wider context of assessing product impacts on water quality. A second aspect of the study was to broaden and refine the characterisation factors (ChF) of detergent ingredients published by the USEtox team and to evaluate differences in calculation approaches within the USEtox tool. This shows a need for a review/evaluation process of USEtox ChFs.

**MO 260**
**USEtoxTM for assessing impacts of cosmetics products for the French regulation of environmental footprint of mass market products**
J Payet, J Rolling, E Maillard
CYCLECO, AMBÉRIEU-EN-BUGEY, France
New environmental regulation for footprint calculation of mass market products distributed in France is currently implemented following the indications of the Grenelle II law. Companies will be requested to provide a quantified assessment of environmental performances of products covering several impact categories such as resource depletion, greenhouse gas (GHG) emissions, water or air pollution. Whilst impact categories are easily quantified using existing methods, new ones such as aquatic ecotox are more complex to address. Nevertheless, this impact category is crucial for environmental footprinting of products directly emitted in water (shampoo, detergents). For those products, the ADEME has identified USETox as the most suitable model for assessing aquatic ecotoxicity in LCA. Applying USETox is promising in terms of results interpretation but requires the development of a specific expertise and the collection of new environmental data for product characterisation. In that frame, Cycleco proposed to the ADEME to provide support for producers and manufacturers of cosmetics or detergent products and ingredients. The developments are done by Cycleco. The overall purpose of the project is to (1) Support companies for assessing the aquatic ecotoxicology footprint of their products; (2) Develop a database providing USETox characterisation factors for cosmetic ingredients and detergents available via the ADEME LCA database for environmental footprinting. Cycleco has already provided to the French ADEME and to the French ministry of Environment a guideline for implementing USETox to be used in the French Environmental Footprinting. Such a large scale experiment for USETox in a considerable step forward, and for that Cycleco was required to produce data enabling large scale use of the model for the cosmetic sector. Thus Cycleco has developed more than 500 new factors in order to cover most of the ingredient used for cosmetics products. In a further development a complete database for cosmetic ingredients will be produce, making USETox easy to use for all cosmetics producers. Beyond the production of the 500 new characterisation factors, the footprinting of several rinsable product (mainly shampoo) have been done on the basis of these new data using LCA, and the main results are presented in the poster highlighting the importance and complexity of assessing ecotoxicity of cosmetics products for the calculation of environmental footprint.

**MO 261**
**Evaluation of toxicity in cotton production and toxicity impact assessment methods**
D Matlock, LL Nalley, ZC Niederman
University of Arkansas, FAYETTEVILLE, ARKANSAS, United States of America
Toxicity from cotton production is a major concern for cotton producers as retailers and consumers begin to incorporate environmental sustainability in their decision making process. We selected five methods that provided index values for each pesticide, without requiring any other parameter input. Four of these methods (CML, Impact 2002 +, ReCiPe, and TRACI) were part of a more complete life cycle assessment methodology and accessible in SimaPro software. The fifth method, EIQ, available in Microsoft Excel, was a method used specifically for assessing toxicity from pesticides. EIQ is a US-based model. Its assumptions and calculations are somewhat more straightforward and explicit. In addition, its impact categories (consumer, farmworker, fish, bees, etc) are more explicit. EIQ also has the most comprehensive list of index values for pesticides used on cotton. However, EIQ's methodology appears to have less capability of distinguishing between magnitude of toxicity of pesticides. It is unclear and beyond the scope of this study to understand how well these methods would perform when comparing cotton production with other agricultural products, or comparing cotton production with other textile production. Ultimately, each of the three methods has its strengths, and is a valuable tool in estimating toxicity from cotton, and all agricultural production. While the methods do correlate, they are not equal. Therefore method selection should depend on the needs of the analysis, such as which pesticides are under study, the type of toxicity being studied, and whether the study is specifically for toxicity from pesticides, or something more broad, including multiple environmental impacts.

**MO 262**

**Life Cycle Impact calculation at global scale and at site-specific scale - damages on coastal waters and soils in the Milazzo Peninsula (North-Eastern Sicily, Italy) -**

M Mey[1], G Quaranta[1], J Duplay[1], A Messina[2]
[1]Université de Strasbourg, STRASBOURG, France
[2]Università degli Studi di Messina, MESSINA, Italy

The Milazzo Peninsula, located in the North-East of Sicily (Italy) is a highly polluted area. Since the last decades, many studies show an increase of the number of cancers and lung infections in this area. The coastal environment is also stressed and an important line of coast is forbidden to swimming due to pollution. Two main anthropogenic activities seem to contribute to the environmental damages: a thermo-electric plant and a refinery.

The main objective of this study is to calculate the damages effectively caused by those two activities, in order to analyze their real contribution to the damages and to understand if there can be other causes.

The Life Cycle Impact Assessment is used in order to better estimate the respective damages on two environmental compartments: the waters (marine and fresh) and the soils.

Seasonal sampling campaigns are realized to collect soils and waters. Initially, heavy metals, trace elements, Polycyclic Aromatic Hydrocarbons and hydrocarbons are analyzed in order to determine the effect and fate factors of the pollutants at a local scale. The analytical methods are ICP"ðMS for the heavy metals and the trace elements, and chromatography for the hydrocarbons, linear and aromatic. In a second time, we calculate the terrestrial and aquatic ecotoxicity generated by these pollutants. Two methods are used. The first one is a "global"method using the software SIMAPRO, european databases and two calculation methods (Recipe and Impact 2002+). The second one is a site-specific approach with a specific characterization of the toxic emissions.

The aims of this poster are: 1) to analyze and interpret the pollutants concentrations that have been found in the different compartments; 2) to assess the impacts and damages upon the chosen compartments using the "global-scaled"method; 3) to assess the impacts and damages upon the chosen compartments by the site-specific approach; 4) to compare the results of both approaches.

**MO 263**

**Regionalized global atmospheric source-to-receptor modeling for LCIA acidification**

PO Roy, G Morin, L Deschênes, M Margni
CIRAIG, MONTREAL, Canada

This paper aims to provide regional worldwide source-to-receptor fate factors for acidifying emissions (NOx, SOx and NHx) within life cycle impact assessment. For this purpose, the three dimensional global scale tropospheric GEOS Chem model was selected. Model simulations were run for the 2005 year of reference. A novel methodological approach was then developed to derive emission-to-receptor matrices with a global 2x2.5 (latitude x longitude) horizontal grid. This new approach overcomes current modeling limitations requiring time-intensive calculations at the expense of a reduced spatial coverage and/or lower spatial resolution. The results of this approach were evaluated against the results from another atmospheric model, EMEP. To do so, the 2x2.5 grids were aggregated at a European country level resolution and compared with source-to-receptor values from the unified EMEP model. Comparison showed good agreement for the NOx and an acceptable agreement for the SOx. For the NHx, close range deposition was systematically lower than EMEP model predictions. Consequently, a correction factor was applied to match EMEP reported local deposition. Comparison also revealed that the source-to-receptor matrices generated with this approach slightly underestimate the overall deposition originally simulated by the GEOS Chem model by about 10 to 17%. This means that when GEOS Chem predicts that 96% of an emission will deposit, this percentage drops to 80% when using the source-to-receptor matrices. Continental fate factors were calculated by aggregating the respective 2x2.5 air grid results using area weighting. Results showed that at a continental level, 40 to 70% of an emission will deposit within the same continent and 10 to 30% will deposit into seas and oceans.

**MO 264**

**Review on methodology for LCIA of marine eutrophication**

HF Larsen
Technical University of Denmark, LYNGBY, Denmark

As part of the ongoing EU FP7 project LC-Impact (www.lc-impact.eu) new life cycle impact assessment (LCIA) methods are going to be developed and tested on industry cases. Among the life cycle assessment (LCA) impact categories in focus are aquatic eutrophication. As related to especially the marine environment very few and restricted attempts have yet been done on trying to include eutrophication in LCA. The aim of LC-Impact is to develop both a global and a spatial (and temporal) differentiated model, as both central fate processes, sensitivities of receiving environments (e.g. differences in limiting nutrient and variations in this over the year) and the resulting damage can show important spatial variations. Both midpoint and endpoint (damage) modelling are included and the aim is to base the damage modelling on dose-response curves expressing the correlation between the (increase in) nutrient concentration and the potentially affected fraction of species in the marine ecosystem. This poster will present a review of the very limited existing attempts on how to include marine eutrophication in LCA and discuss alternative methodologies on how to model the environmental mechanism of this impact category.

**MO 265**

**Globally applicable, spatially explicit assessment of non-toxic air pollutants**

P Preiss[1], R Friedrich[1], R van Dingenen[2], FJ Dentener[2], S Torras-Ortiz[1], J Roos[1], W Müller[1]
[1]University Stuttgart, (IER) I. Energiewirtschaft und Rationelle Energieanwendung, STUTTGART, Germany
[2]Joint Research Centre -Ispra, Institute for Environment and Sustainability, CCU, ISPRA, Italy

**1. Introduction**

This paper presents intake factors (iF) and characterization factors (CF) regarding human health effects for the pollutants NH3, NMVOC, NOx, SO2, primary particulate matter (PPM), and also accounting for the reactants ozone and secondary inorganic aerosols (SIA). Research on LCIA for transboundary pollutants have been reviewed and it is suggesting that spatially differentiated fate modelling may be crucial. The present work aims to fill the gap of consistent global modelling by developing an approach to derive globally applicable and spatially explicit values, and by providing a comparison between models with a different degree of spatial resolution.

**2. Materials and Methods**

Within the ongoing EU-funded project LC-IMPACT (2010-2012) the "Development and application of environmental Life Cycle Impact assessment Methods for imProved sustAinability Characterisation of Technologies"is pursued. Within the area of "Non-toxic pollutant impacts"the objective is to develop globally applicable, but spatially explicit, life impact assessment methods and characterization factors.

Within the TM5-FASST modelling framework, the world is divided into 54 regions. Each region serves as a source region and each grid cell (resolution 1°x1°) of the whole world serves as receptor region. Population data and concentration response functions are applied in order to calculate the iF and relevant diseases. A new methodology for evaluating emissions due to transport activities has been applied taking into account the urban increment for emissions in urban areas. Finally, the application of monetary valuation is demonstrated in order to derive specific damage cost estimates per unit of emission by including and excluding equity weighting.

**3. Results**

A detailed comparison will be made between iFs derived by the TM5-FASST model and by the EcoSenseWeb integrated assessment tool in order to assess the inherent uncertainties and implicit variability in the estimates. For primary particulate emissions specific conditions (i.e. height of release, adjacent population density and distribution) are taken into account, and therefore, iFs and CFs are calculated for several archetypes such as, urban, non-urban and remote sources with different height of release. Finally, iFs and CFs suggested in different LCIA methods have been compared with the findings of this work and further results from LC-IMPACT, as well.

**MO 266**

**Development of damage assessment method for biodiversity caused by global warming**

L Tang, N Itsubo
Tokyo City University, YOKOHAMA, Japan

According to Millennium Ecosystem Assessment (2005), climate change is recognized as one of the main factors of biodiversity damage. Though several damage assessment methods used in LCIA have been developed to quantify the damage of biodiversity caused by land use and chemical exposure, there are still few methods for climate change. Therefore the aim of this study is to develop a damage assessment method of biodiversity caused by climate change using EINES (Expected Increase in Number of Extinct Species) as an indicator of extinct risk.

The procedure of the method is as follows. First the future temperature change and the amount of rainfall change caused by CO2 emission were predicted using MAGICC (Model for the Assessment of Greenhouse-gas Induced Climate Change) model. Secondly, the change of future distributions of species by future climate change was projected based on bioclimatic modeling (also called niche-based model). Then we linked the results of bioclimatic models (shifts and reductions in species' ranges) to extinction risk based on the IUCN Red List Criteria (IUCN 2001). Thirdly, EINES was calculated with an inverse of the time (years until extinction) which was estimated from extinction risk of IUCN Red List Criteria. Finally, the extinct risk of Japanese vascular plant was estimated based on the method.

**MO 267**

**Accounting for the potential value of temporary carbon storage: the issue of choosing relevant time horizons**

SV Jørgensen, MZ Hauschild
Technical University of Denmark, LYNGBY, Denmark

Currently, climate change is an impact category of great importance in LCA, but the issue of possible climate change mitigation potential from temporary carbon storage is not considered consistently. Several proposals for accounting for the climate change mitigation value associated with temporary carbon storage have been made; however most of them are based on an interpretation of the 100-year time horizon, adopted from the Kyoto Protocol. The consequences of this interpretation are discussed here, and it is illustrated how such a relatively short time horizon is hiding the long-term impacts of anthropogenic released $CO_2$ in the atmosphere, thus risking to 'green wash' the use of fossil fuels by employing temporary carbon storage as compensation for their release. Based on an overview of the complete carbon cycle on Earth, another approach is suggested here: For temporary carbon storage to provide real long-term climatic benefits, storage should at least be ensured for a thousand-year timescale, in order to facilitate simultaneously removal of carbon from the near-surface layers of the carbon cycle down to deeper layers, from where it is not as easily released again. However, as there is also a key issue of not crossing potential nearby climatic tipping points, there may also be a climatic benefit from more short-term storage solutions, buying society time to become more carbon neutral before the carbon is released. Such short-term storage value should however be accounted separate from the long-term climatic benefits, illustrating that they address two different parts of the climate change problem.

**Environmental performance of electric taxis compared to diesel taxis in Copenhagen: a case study including the impact of traffic noise upon human health**

V Franco[1], TD Cruz[2], A Beylot[2], J Payet[2], D Garraín[3], R Vidal[4], C Munõz[4]
[1]Institute for Environment and Sustainability, ISPRA, Italy
[2]CYCLECO, AMBÉRIEU-EN-BUGEY, France
[3]CIEMAT, MADRID, Spain
[4]Universitat Jaume I. Engineering Design Group, CASTELLÓN, Spain

Noise may well be one of the most pervasive issues affecting human well-being and yet it is largely ignored in everyday LCA practice. The marginality of noise within LCA can be explained by the particular characteristics of noise emissions as a pollutant, and by several methodological shortcomings (a problematic selection of health effects and dose-effect relations, the nonlinearity of impacts) that still hinder the inclusion of transport noise as an established impact category within LCA.

In this work, the environmental performance of a hypothetical taxi fleet is assessed for the city of Copenhagen. Two scenarios are compared: the first one considering diesel vehicles, the second one considering full electric vehicles (EV). Both scenarios take into account best available technologies. The impact categories covered include global warming, non-renewable cumulative energy demand and impact upon human health. Moreover, this work presents the first real-world application of the assessment method for the inclusion of the impact of road traffic upon human health within LCA proposed by Franco et al. Said methodology builds upon the incremental approach to assessments proposed by Müller-Wenk, whose calculation assumptions and procedures are modified in order to improve the accuracy of assessments. The IMAGINE traffic noise emission model is used to model the emissions of EV and Diesel taxis, and the resulting sound power emission levels are computed. The use of said traffic noise emission model leads to faster, more versatile assessments of health impairment due to traffic noise.

Earlier quantifications of health damages attributable to traffic were made in terms of DALY units. In this research study, self-reported annoyance -derived from the dose-response functions developed by Miedema et al.- is proposed instead as the primary indicator for health impairment due to traffic noise. Hence, the midpoint indicator is still comparable with other endpoint categories. Moreover, geo-referred information reported by EU member states can be easily included in the exposure assessment. This straightforward use of indicators termed in plain,

natural language (e.g. '[additional] number of persons annoyed by traffic noise') has the benefit of presenting results in a manner that is intelligible to both policy-makers and the general public, while being comparably effective in communicating the impacts of noise.
Keywords: noise, electric vehicles, LCA, number of persons annoyed

**MO 269**
**Endpoint characterisation factors (CF) in the unit of [DALY per Bq] and damage costs [Euro per Bq] for selected radionuclides releases during normal operation of nuclear fuel cycles**
P Preiss, R Friedrich
University Stuttgart, (IER) I. Energiewirtschaft und Rationelle Energieanwendung, STUTTGART, Germany
**Characterization Factors**
A simplified approach for characterization factors (CF) for assessment of potential human health impacts related to radioactivity for a selected number of radionuclides has been developed. Updated data on relation between Bq and manSv, according to UNSCEAR reports from 1993 and 2000 [1], has been used. This approach is site generic because for the UNSCEAR reports typical population densities for certain processes have been assumed. The dispersion and exposure modelling, i.e. the relation between emission [Bq] and dose [manSv] is included in these dose factors. The approach has been implemented in the EcoSenseWeb tool [2] in order to evaluated impacts due to nuclear fuelled electricity generation. However, the CF can also be applied to other sources with similar environmental conditions.
**Effect Factors**
The factors relating collective dose [manSv] to human health impact, are based on the ICRP60 [3] recommendations, i.e.:
0.05 cases per manSv for fatal cancers
0.12 cases per manSv for non-fatal cancers and
0.01 cases per manSv for hereditary defects.
Moreover, updated factors from ICRP have been compared.
**Damage Factors**
These endpoints are weighted in the following way
1.62 DALY per non-fatal cancers
16.2 DALY per fatal cancers and
37.5 DALY per hereditary defects.
In addition, latest WHO 2002 statistics are applied, ensuring a consistency with the treatment of cancers used for the human toxicity category, with average of 11.5 DALY per case of cancer against 17 DALY per case, as reported by [4].
The results have been compared with other LCIA methods, e.g. based on [4] or [5], on the basis of DALY per unit of activity emission.
**Damage Costs**
For monetary valuation the DALY have been multiplied by the value of a life year lost (VOLY-acute) of 60,000 $Euro_{2000}$ per year (based on l[6]).
Finally, discounting with declining discount rate is applied to the most important substances, i.e. Rn-222, H-3 and C-14.

**Impacts of agricultural land use changes on ecosystem services**
R van Zelm[1], M van der Velde[2], S Leduc[2], M Obersteiner[2], MAJ Huijbregts[1]
[1]Radboud University Nijmegen, NIJMEGEN, The Netherlands
[2]International Institute for Applied Systems Analysis, LAXENBURG, Austria
Land use is considered to be an intensive human activity that aims at exclusive use of land for certain purposes, such as agriculture, and adapting the properties of land areas in view of these purposes. All basic land use activities result in either damage to or benefits for ecosystem quality. The ecosystem quality can be expressed in certain ecosystem services, such as carbon stock, erosion regulation, and nitrogen cycling. Over the years the idea has been evolving that life cycle oriented methods should encompass spatial analysis of ecosystem services, since these form the basis of planetary activities and human well-being. In this research we focus on the changes in ecosystem services due to the expansion of land area used for agriculture in need to increase production of rapeseed, corn, and other crops. The objective of this research is to provide quantitative estimates for the changes in ecosystem services, that can be applied for life cycle assessment (LCA) purposes. To calculate this, the Environmental Policy Integrated Climate model (EPIC) will be used, which applies the global land use database Global Land Cover (GLC) 2000. EPIC is a global spatial and temporal agri-environmental model, which simulates bio-physical impacts on homogenous response units characterised by altitude, slope and soil class. The major processes included in EPIC are weather simulation, hydrology, erosion, nutrient and carbon cycling, pesticide fate, crop growth and competition, soil temperature and moisture, tillage, cost accounting, and plant environment control. The output of the model can be crop yields, hydrology (PET, runoff, percolation), sediment transport, N-leaching, green house gases, and soil carbon sequestration. Model output can be aggregated to e.g. province, country, ecozone, or biome level. The poster will show results of changes in CO2 emissions, erosion potential, and biomass stock due to an increase in crop production in various world areas. These results can serve as input in life cycle inventories or serve as midpoint indicators in life cycle impact assessment.

**MO 271**
**LCA biodiversity indicators using cocoa (Theobroma cacao) as a model crop**
MK Herzog, LL Nalley, EC Cummings, MD Matlock
University of Arkansas, FAYETTEVILLE, United States of America
Biodiversity conservation is one of the hot topics of today's research and policy developers. Cocoa production is reaching an all-time high and as its production increases, cocoa forests offer unprecedented opportunities for biodiversity conservation through production as well as a continued threat to destroy the very biodiversity that it could help conserve. There is a definite need to develop a metric for measuring biodiversity in cocoa plantations; literally dozens of articles have been written on the value of biodiversity, the conservation benefits, the pest control, the longevity and sustainability it adds to cocoa production, and the possible economic benefits of cocoa. Corporations, farmers, and governments looking to the future want to reap these benefits and select a crop system for cocoa that will help eliminate the boom and bust cycle that it has suffered and will be sustainable over centuries. For these reasons and more, a metric is needed to assess the biological diversity found in cocoa plantations under different management systems.
One method for assessing biodiversity posited has been to survey target species that are deemed "ecologically significant", keystone species who may reflect a greater total biodiversity or greater number of ecosystem services proffered. Determining which species or taxa should be targeted presents significant difficulty and requires extensive knowledge of the particular ecosystems, and cocoa is now a global crop. Traditional indices of biodiversity may also help, but they tend to be hamstrung by specific requirements of the ecosystem to which they are applied. Species counts by taxa, by species, along with relative abundances may profer a sense of species richness and species diversity. Unfortunately, such overarching ideals are not feasible due to the dearth of primary data from the disparate regions and production systems.
Further considerations also include the necessity of measuring endemic biodiversity to total biodiversity. If the cocoa farms are considered biologically diverse, but the majority of the species are exotics, one of the original purposes of preserving biodiversity in the region has become moot. As with all factors in LCA, for a method of cocoa production to be touted as a "best practice"or as sustainable, a metric for biodiversity must be at least understood before establishment. That metric is what this research attempts to develop through the address of the aforementioned issues.

**MO 272**
**Water use impacts in life cycle impact assessment**
AR Brown, MD Matlock, RZ Johnston
University of Arkansas, FAYETTEVILLE, United States of America
Current LCA methodology is lacking in the area of evaluating the environmental impacts of water use. Typically freshwater consumption is presented in the form of a volumetric quantity. Without further information regarding type of water use, location of water withdrawal, indication of consumptive versus degradative use, and in-stream or off-stream use with respect of the quantity of water reported tells little about the impact. Furthermore, it is important to assess the status of the local environment which the volume of freshwater is withdrawn.
There is currently no agreed standard which to assess water scarcity. However, there are many proposed indicators used to assess water resources vulnerability. The majority of water stress indices are a function of freshwater demand and supply. In order to accurately assess freshwater stress or scarcity, an evaluation must be done at the basin level. Idealistically, water consumption by each sector (agricultural, domestic, and industrial) would be easily measured and available at the basin level for the entire globe. However, such data does not yet exist.
Other risk indices incorporate per capita water demand, environmental water requirements, and physical and economic water scarcity. Each index provides a different approach to assessing water resources vulnerability and are all informative evaluating corporate risk. By incorporating multiple indicators into the LCIA for water use, a comprehensive evaluation of local freshwater vulnerability can be made. Only after the status of local freshwater resources is determined, can the impacts of water use be determined.
Developing a method to quantify the variables surrounding the status of local freshwater resources is critical in order to evaluate the impact of freshwater use.

**MO 273**
**Toward consistent emergy calculations with LCI databases: implementing the emergy algebra**
E Benetto
Public Research Centre Henri Tudor, ESCH SUR ALZETTE, Luxembourg
Life Cycle Inventory (LCI) databases like Ecoinvent are used for evaluating resource depletion and ecosystem quality within Life Cycle Assessment (LCA). LCA ignores, however, part of ecosystem services (material and energy flows) that are damaged by human activities and should therefore be included in the assessment. Emergy concept could fill this gap. Emergy is defined as the quantity of energy (solar energy, in MJse) directly and indirectly necessary to support a given system and its level of organization, providing a measure of the global Nature's efforts required to make a product or service available. The main drawback hampering the applicability of emergy calculations is the lack of detail and transparency of its allocation procedure. The use of LCI database for emergy calculation is therefore highly relevant to solve this issue. Unfortunately, Emergy requires a set of algebric allocation rules that are completely different to those applied in LCI. Two major problems are to be faced: 1) all the multi-output processes (and related natural resources) shall be included without LCA-like allocation but even though dealing with a square A matrix; 2) specific rules for co-products, splits and feedbacks make allocation at each node of the network depending on the surrounding nodes and links. This study provides a consistent conceptual and technical framework to definitively solve these problems, which is illustrated through an example of complex system based on ecoinvent unit processes. Datasets of the co-products of a multi-output process are kept separated but are assigned the full amount of inventory data of the multi-output process. The additional co-product generated by each dataset is then calculated. Conventional LCI calculations are performed to obtain the matrix s x A including all the mass and energy flows of the network. A novel algorithm for emergy algebra has been developed in Matlab to this purpose and applied to the s x A matrix. The emergy results obtained have been successfully re-calculated using Emsim, software for emergy calculation, by drawing the network as a graph. The framework is therefore validated on a complex case study. The approach is being applied to the whole Ecoinvent database. The framework will allow consistently introduce emergy in LCI and LCA, sound calculation of specific emergy of products (impossible task so far), generating a huge impact in the practice of sustainability assessment.

**MO 274**
**The analysis of environmental impacts**
J Koroneos[1], M Loizidou[1], G Tsatsaronis[2]
[1]Unit of Environmental Science and Technology, ATHENS, Greece
[2]Institute of Energy Engineering, BERLIN, Germany
Environmental Impact Assessment (EIA) is an issue of major concern for every industry, for every nation and for every product that is in the market. The EIA constitutes one of the very important steps of Life Cycle Assessment (LCA). EIA constitutes one of the four steps in performing LCA. The definition goes further and includes the evaluation and implementation of opportunities to affect environmental improvements. It is very important to understand the nature and the limits of the impacts in order to be able to proceed with a plan to improve them. The environmental impacts occur because during the process there is a material and energy transformation that leads to the increase of the entropy. This will lead to various emissions and wastes. However, the environmental impacts could be divided into two categories: The impacts that are impeded in the process, that are unavoidable, and their magnitude depends on the efficiency of the process;

the impacts that are peripheral, the impacts affected by factors located in other than the main processes. The impacts that are included in the second category, the peripheral impacts, could be easily minimized with the implementation of certain actions. The impeded impacts require a very thorough knowledge of the production process in order to be able to set up a program of improvements.
This work will analyse these two environmental impact categories and show examples of production processes.

**MO 275**
**Using multi-criteria decision making models in the framework of LCIA analysis**
A Matarazzo, MT Clasadonte
UNIVERSITA' DEGLI STUDI DI CATANIA, CATANIA, Italy
Life Cycle Impact Assessment (LCIA) focuses on a charge of consumption and emissions produced during LCI to specific categories of impact attributable to known environmental effects. Moreover, also aims to quantify, with appropriate characterization methods, the magnitude of the overall contribution to the process or the product has against the effects concerned. The structure of a LCIA consists of some compulsory elements (mandatory elements) which convert the results of inventory in appropriate indicators that can be used directly or as a basis for optional subsequent evaluations LCIA.
In accordance with approved international standards, the study has to complete the selection of environmental effects to be considered, the results of the allocation being chosen LCI to environmental effects (classification) and the calculation of different indicators category, such as Nutrification Potential, Ozone Detection Potential, Global Warming Potentials, etc. While, the comparison between environmental indicators calculated with reference values (normalization) and the determination of the importance of individual environmental effects (weighing) are optional. In a lot of approaches, such as Eco-indicator method and Panel approach, the values of different environmental impact indicators are aggregated by weighted sum, obtaining a value that allows us to rank or classify the alternatives.
This implies, among others, the elicitation of trade-off weights and to accept the complete compensation among evaluations, for example good values on some indicators can be perfectly balanced by bad evaluations with respect to other indicators.
In this paper, we emphasize the possibility to aggregate multi-criteria evaluations using different approaches and operators, actually more suitable for environmental problems. More precisely, values of different indicators can be aggregate in a more flexible way, using operators not necessarily perfectly compensatory, allowing partial compensation and/or not transitive preferences, including also the possibility to model interactions among criteria. In the case of sorting, i.e. ordinal classification, for example, some reference profiles or only exemplary classification of a sample of well known objects can be introduced as preference model of decision maker. The output of these models can be outranking relations or decision rules, whose appropriate exploitation allows to built up the recommendation (choice, ranking or sorting) required.

**MO 276**
**Life Cycle Impact Assessment: research needs and challenges from science to policy making**
M Brandão[1], S Sala[1], MZ Hauschild[2], R Pant[1], D Pennington[1]
[1]Joint Research Center European Commission, ISPRA (VA), Italy
[2]DTU Management Engineering - Technical University of Denmark, COPENAGHEN, Denmark
In the Communication on Integrated Product Policy (IPP), the European Commission committed to produce a handbook on best practice in Life Cycle Assessment (LCA). In this context, JRC led a "science to policy"process which resulted in the ILCD International Reference Life Cycle Data System (ILCD) Handbook. ILCD Handbook is a series of detailed technical documents, providing guidance for good practice in Life Cycle Assessment in business and government. For Life Cycle Impact Assessment (LCIA), the Handbook provide guidelines to methods and assessments to analyse the emissions into air, water and soil, as well as the natural resources consumed in terms of their contributions to different impacts on human health, natural environment, and availability of resources.
Those guidelines come from a comprehensive process of selection of methods based on a set of scientific and stakeholder acceptance criteria and involving extensive hearings of domain experts, advisory groups and the public. In this "from science to policy"process a number of research needs, critical issues and challenges for Life Cycle Impact Assessment emerged.
Robustness of models and reliability of characterisation factors must be the basis for further development in Life Cycle Impact Assessment (LCIA). To foster the robustness and acceptability of existing and new methods, some of the points under discussion will be presented

## LC02 - Developments in Life Cycle Sustainability Assessment (LCSA)

**MO 282**
**Development of a Sustainability Business Assessment (SBA) tool in British American Tobacco (BAT) to support sustainable decision making**
NG Rehman, M Balogh, S Havercroft
British American Tobacco, SOUTHAMPTON, United Kingdom
This poster summarizes some of the tools and business enablers being developed in BAT to support sustainable decision making. The focus of the tools is on the provision of information to better understand the consequential supply chain impacts of product and process design.
Life Cycle Analysis (LCA) includes the 'seed to stub' model, and has been used to develop the Sustainability Business Assessment (SBA) tool across Group Research & Development (GR&D). The SBA has been incorporated into project management in the design community, and provides a disciplined approach towards the assessment of the environmental, social and economic implications related to a new product, process, material or innovation to the business. These studies compare existing impacts to those created by the introduction of a new material or innovation, and provide an opportunity to mitigate consequential impacts along the supply chain.
The environmental part of the SBA is delivered through LCA studies. For example, water and energy use, and emissions to air and water. The social part of the SBA includes the provision of health and safety procedures, and use of robust scientific methods.The economic part of the SBA includes cost of machinery, processes and capability and continuity of supply. A case study illustrating the use of the SBA will be presented.
The LCA database also enables the creation of Interactive-reports which allow supply chain communities to run business scenarios and compare the environmental impacts (for example: CO2 impacts related to transport decisions).

**MO 283**
**Use of aluminium vs. iron metals in the car industry. Comparative evaluation made by using LCA and external costs methodologies.**
L Cutaia[1], G Mastino[2]
[1]ENEA, ROMA, Italy
[2]Amici della Terra (Friends of the earth Italy), ROMA, Italy
Aim of the study is the evaluation of the environmental advantages and potential reduction of external costs that can be achieved through substitution of the traditional iron based materials (pig iron and steel) with aluminium in the production of road transport vehicles. Data about circulating car and lorry fleets, mileage, vehicles composition, etc., refer to year 1997.
Quantification of environmental impacts has been carried out by using LCI data provided with the SimaPro software.
Results show that primary aluminium production determines external costs per unit mass higher than those due to iron and steel production (3.900 lire97/kg, 460 lire97/kg, 760 lire97/kg respectively). However, secondary (80%) aluminium production determines much lower costs (700 lire97/kg), very similar to those than iron and steel. These data indicate the importance of aluminium recovery and recycling.
Fiat Research Centre states that for a 1000 kg car a weight reduction of 10% determines a consumption reduction of 6% , similarly to what behold Alcan Europe and other in the document "Aluminium for the future generations".
Two different scenarios have been simulated that include a short term modest weight reduction (10%, scenario A) and a mid term higher weight reduction (20%, scenario B): for both scenarios has been assumed the option of using primary (A.1, B.1) and secondary (A.2, B.2) aluminium in substitution of iron and steel.
The study indicates that a vehicle weight reduction obtained through a progressive substitution of iron with aluminium in some components determines a reduction of the external costs evaluated over the whole vehicle life.

**MO 284**
**Development of an evaluation method of sustainability for events from the view point of environmental, economic and social aspects**
H Yamaguchi, Y Ono, N Matsunaga, K Horiguchi, L Tang, N Itsubo
Tokyo City University, YOKOHAMA, Japan
Towards realizing the sustainable society, it is becoming an urgent task to estimate the various kinds of events; sports, conference, music festival, etc. Based on tripod aspects of environmental, economic and social issues, an evaluation method of sustainability for events is developed.
First, all kinds of the data of event (construction of temporally structure, goods, food and drinks, services, transportation, etc) are collected. Then resource consumption of fossil fuel, minerals, water and economical ripple effect are calculated using the database developed by Tokyo City University based on IO method. CO2 emission is calculated using 3EID and process method.
For environmental aspects, Life Cycle Inventory Analysis is performed with resource consumption of fossil, mineral, and water, and GHG emission. Then Life Cycle Impact Assessment is performed with LIME2.
For economical aspects, economic ripple effect analysis is performed considering employment using IO method.
For social aspects, considering added value, water consumption, CO2 emission by a event, influence of human health, education, food production, water for living, social assets, then social impact assessment is performed by calculating the influence for the HDI(Human Development index).
Then sustainability assessment for events is performed by combining and arranging the tripod evaluation above for environment, economic and social aspects.
A sustainability evaluation for a sports event is shown as an exemplification of this method.

**MO 285**
**Social Life-Cycle Assessment of waste management options. Some preliminary results.**
D Russi[1], A Bala[1], A Lehmann[2], P Fullana[1]
[1]Escola de Comerç Internacional, BARCELONA, Spain
[2]Technical University Berlin, Department of Environmental Technology, BERLIN, Germany
This paper presents the preliminary results of a Social Life-Cycle Assessment (S-LCA, as defined by the UNEP-SETAC Guidelines) of the available waste management options in Spain and Portugal, which is performed within the framework of the LIFE+ project FENIX - "Giving packaging a new life"(2010-2013).
The integration of social aspects in environmental analyses is increasingly being recognized as very important (Benoît and Mazijn, 2009); however, S-LCA is still in its infancy and needs to be consolidated and tested in a wide range of real case-studies. Since most social impacts of technologies and management options depend very much on the local conditions (e.g. economy, social and institutional structure, culture), the choice of the indicators has to be made according to the characteristics of the problem to be tackled.
In our case, a first list of 13 impact categories were defined, based on a thorough literature review. Then, questionnaires were filled out by three groups of social actors, namely: (i) 10 Spanish Regional Governments, (ii) 20 Spanish and 9 Portuguese Management Units (MUs), and (iii) both the Spanish and the Portuguese green dot holders. The 13 impact categories were thus given individual scores by the representatives of the consulted social actors, leading to a final ranking, which was obtained selecting the first five categories in the ranking of each group of social actor. Finally, an indicator was chosen for each impact category, in order to assess the impact in the respective social dimension of the available waste management options.
The first preliminary conclusions are as follows: 1) when analysing the social impact of technologies or management options, it may be difficult to adopt a life cycle approach, because impacts taking place in different stages of the supply chain are difficult to evaluate and to aggregate in one indicator; 2) in some cases, data availability represents a serious hindrance; 3) it is most important to adopt a large range of point of views, involving different categories of social actors.

**MO 286**
**Energy sustainability in medium and small communities**
P Castagnoli, G Dotelli
Politecnico di Milano, MILAN, Italy
The Covenant of Mayors (CoM) is a European initiative by which towns and regions voluntary commit to reduce their CO2 emissions. The formal commitment is to be achieved through the implementation of a Baseline Emission Inventory (BEI) and a consequential Sustainable Energy Action Plan (SEAP).
The Comunità Montana Valle Sabbia (CMVS) is a group of municipalities located in the northern area of Brescia district (Italy), between the Garda lake and the Alps, that have joined the

CoM. In the area of CMVS the industrial sector is well developed, so there is little improvement margin with regard to CO2 reduction, as demonstrated by BEI analysis; on the contrary, this study has highlighted that consistent benefits could come from the reorganization of residential and tertiary sectors in some municipalities and of the residential sector and public transports in others.
Based on results obtained during the BEI step, the SEAP has identified a group of actions to reduce energy consumption and GHG emissions in the CMVS: improvement of buildings envelope to reduce thermal transmittance; replacement of old and low-efficiency central heating mainly in municipal buildings; substitution of present municipal public lighting with low-energy consumption systems; integrated photovoltaic systems on buildings to reduce grid electricity demand.
Besides these deeds, all concerning the sphere of public tertiary and private residential sectors, which anyway could not be sufficient to comply to the EU directive 20/20/20, it has been suggested a PV power plant of 6 MW, able to serve many Municipalities, that would help reduce actual emissions in the atmosphere.
In accordance with the CoM guidelines the estimates were carried out following the Life Cycle Assessment method, able to provide a complete evaluation about both current situation and actual benefits as a result of the proposed actions, without which the result is underestimated.

## PE01 - Data-driven, knowledge-based, and QSAR modelling in ecotoxicological assessment

**MO 290**
**Results evaluation in spatial decision models**
O Cadiach Ricoma, A Passuello, J Rovira, M Schuhmacher, Y Pérez
Universitat Rovira i Virgili, TARRAGONA, Spain
The use of spatial decisions support systems for environmental management allows considering expert knowledge though the integration of multiple criteria in a GIS basis. As environmental systems are highly complex, these models present an inherent uncertainty. Due to this fact, results evaluation must be performed to check if the model outputs correspond to stakeholders' expectations. These methods allow evaluating how the information given in model's input affects its outputs.
The objective of this work was to perform results evaluation in GIS. For that, the exploratory method was applied to a case study of land classification. The first step was developing scenarios based on the initial model. For each scenario, the weight of one criterion was set to zero and the weights of the remaining criteria were redistributed accordingly. Then, the results for each scenario were compared to the initial map, identifying the changes in each pixel.
The results allow a better understanding of the developed model. Besides that, the use of GIS allows presenting the results in a graphic way, facilitating its evaluation. This method has proven to be useful for model calibration.

**MO 291**
**Determination of polycyclic aromatic hydrocarbon emission sources from Cartagena Bay, Colombia**
B Johnson-Restrepo
University of Cartagena, CARTAGENA, Colombia
The Cartagena bay is an estuarine in the Caribbean Sea which received fresh waters from Magdalena river through the Dique channel. Several commercial activities are developed along of this Bay such as petrochemical industries, harbours, and tourist attractions. However, all these activities produce an environmental implication that it has not been measured yet. Therefore, 16 priority polycyclic aromatic hydrocarbons (PAHs) analyzed by gas chromatography coupled with mass spectrometry (GC/MS) in sediments from Cartagena bay were used to determinate the possible emission sources through approach of multivariate analysis to know what can be produce the major impact. PAHs are largely produced by mean of the combustion or pyrolysis of organic matter. High levels of PAHs in the environmental can be related with the risk to develop cancer in human. Results showed that the profile of PAHs of the Cartagena bay implicate that the pollution is caused by oil spill, combustion of gasoline and diesel.

**MO 292**
**Modeling toxicity endpoints using artificial neural network ensembles (II)**
AC Lee, R Fraczkiewicz, WS Woltosz
Simulations Plus, Inc., LANCASTER, United States of America
Today and for the foreseeable future, it is important to utilize the best possible analysis of knowledge (both data and technique) to save and protect the environment. The use of in silico models are at the forefront of the battle surrounding the development and waste management of chemicals. A common theme in Green chemistry is the application of useful models to reduce the need to perform costly, time consuming, and often inhumane in-vivo experiments, such as lethal dose/concentration and Draize tests for skin or eye irritation. Unfortunately, making a useful toxicity model is often more difficult than it sounds mainly due to the involvement of multiple biological mechanisms and conflicting experimental measurements.
In this work, artificial neural network ensembles (ANNEs) were used to generate robust models for a number of toxicity endpoints including acute rat toxicity (LD50), fathead minnow LC50, Tetrahymena pyriformis IGC50, Daphnia magna LC50, reproductive/developmental toxicity, and bioconcentration factor. These results are compared with other QSAR methodologies used in the Environmental Protection Agency's Toxicity Estimation Software Tool (T.E.S.T.) v3.3 which include multiple linear regression, hierarchical clustering, nearest neighbor, and other similarity-based methods. In almost all comparisons made using the training and external test sets specified by the EPA, ANNEs proved to be more robust and showed superior performance in terms of RMS error for regression models and false rate for classification models. Accuracy within the applicability domain of each model was further improved by using Kohonen mapping (independent of the endpoint values) to select new training and external test sets.
Finally, all models were optimized by applying focused curation techniques beyond averaging the available experimental data. One curation technique not often publically addressed is the examination of predicted outliers in both training and test sets identified by preliminary models. Another technique is to verify that the structure of each chemical exists in one or more reliable data sources. If a structure cannot be identified the chemical is flagged for further curation. Examples and the relative finalized models are discussed, as the techniques can be useful when dealing with large data sets where rigorous literature mining is not feasible.

**MO 293**
**Predicting species sensitivity distributions of chemicals with limited ecotoxicity data**
W Naito, K Kamo, BL Lin
National Institute of Advanced Industrial Science and Technology, TSUKUBA, Japan
Efforts to reduce the risk of a certain compound to aquatic life may increase the total risks arising from alternative compounds. In order to reduce the total risks arising from the use of chemical compounds, we need to quantify the risks of the target and alternative compounds with common metrics. Species-Sensitivity Distribution (SSD) is a powerful tool that can provide a common metric for quantifying ecological risk of compounds. Derivation of SSD is commonly hampered by lack of ecotoxicity data. In this study, we propose an approach to fill data gap on ecotoxicity data of compounds to allow us to compare and evaluate risks of the target chemical and its alternatives with SSD-based common metrics. We have compiled available acute aquatic data and calculated SSDs for several dozen of chemicals. The calculated SSDs were categorized by different chemical classes. Based on the categorized data, we have developed a linear model to generate SSDs of chemicals with limited ecotoxicity data. Hazardous concentrations (HCs) from the estimated SSDs using the linear model were well predicted within a factor of 2 for Class 1 (non-polar narcosis) chemicals. The proposed approach has potential for predicting SSDs for chemicals with limited ecotoxicity data. A SSD prediction using bayesian approach and the domain of applicability and the management of uncertainty are discussed during presentation.

**MO 294**
**Physicochemical characterization of mixed polybrominated/polychlorinated derivatives of Persistent Organic Pollutants with QSPR**
K Gaworski[1], A Gajewicz[1], A Rybacka[1], K Odziomek[1], M Haranczyk[2], T Puzyn[1]
[1]University of Gdansk, GDANSK, Poland
[2]Computational Research Division, Lawrence Berkeley National Laboratory, BERKELEY, United States of America
Mixed polybrominated/polychlorinated Persistent Organic Pollutants (Br/Cl-POPs) are formed in various natural and anthropogenic processes. Since empirical studies confirm that its physicochemical properties and biological activity are comparable to the properties of their polychlorinated and polybrominated counterparts. it is evident that Br/Cl-POPs may also have negative effects on the wildlife and human health. Regarding that environmental concentrations of Br/Cl-POPs in all environmental compartments are increasing, detailed studies aimed at performing a comprehensive risk assessment for this class of mixed POPs is of special interest.
The main problem in the risk assessment for mixed Br/Cl-POPs is the huge number of congeners, theoretically possible substitution combinations. On one hand, this leads to difficulties with identification of the particular congeners present in the environmental samples. On the other one, physicochemical characterization of such a large number of compounds could not be performed with empirical methods in a reasonable time period.
The problem can be solved by employing such computational techniques as Quantitative Structure-Property Relationships (QSPR) modelling combined with combinatorial chemistry. We generated all possible polybrominated/polychlorinated congeners for six groups of organic compounds (benzenes, PXBz; biphenyls, PXBs; dibenzo-p-dioxins, PXDDs; dibenzofurans, PXDFs; diphenylethers, PXDEs; naphthalenes, PXNs) with the ConGENER software package. This resulted in 23,739 mixed congeners in total. Then, molecular geometries of the congeners were optimized and quantum-mechanical descriptors were calculated at the level of semi-empirical PM6 method. Based on these descriptors and the existing or newly developed QSPR models, we predicted logarithmic values of five physicochemical properties, including: Henry`s law constant (log KH), subcooled liquid vapor pressure (log PL), solubility in water (log SW), and three partition coefficients (log KOW, log KOA and log KAW). Finally, we have estimated the environmental behavior of the studied compounds by comparing the values of the predicted properties with the corresponding values for well-studied polychlorinated and polybrominated POPs.

**MO 295**
**Global vs. local QSPR models for persistent organic pollutants**
T Puzyn, A Gajewicz, A Rybacka
University of Gdansk, GDANSK, Poland
Experimentally determined data on the key physicochemical parameters for halogenated congeners of Persistent Organic Pollutants (POPs) are available for a limited number of compounds. In the absence of experimental data, a range of computational methods can be applied to fulfil those data gaps. One of the widely used techniques is Quantitative Structure-Property Relationships (QSPR) approach. There are two ways to develop the QSPR models: using a more complex global model or fitting a simple local model that covers a specific class of chemically related compounds. The main purpose of the study was to investigate, if local models have significantly better explanatory and predictive ability than global models with wider applicability domains.
We have compared in pairs predictive performance of global and local QSPR models to predict the water solubility, vapour pressure and octanol-water partition coefficient of the Cl/Br-substituted congeners of benzenes, biphenyls, diphenyl ethers, dibenzofurans, dibenzo-p-dioxins and naphthalenes. The comparison was based on the measurement of the goodness-of-fit, robustness and prediction ability recommended by the Organization for Economic Cooperation and Development. In addition, we employed t-Student's pairwise test to analyze statistical significance of the models' residuals.
The comparison between the predictive performances of local and global models, indicated that the local models fit better to the experimental values and were more precisely than the global ones. However, any statistically significant differences between the measured and calculated values for both types of models (local and global) were not found. Based on the obtained results, we concluded that since global models fulfil all quality criteria recommended by OECD, they should be applied in practice in state of more time consuming procedure of modelling the particular groups of POPs one-by-one. This is extremely important from the economic point of view, especially when the number of novel chemicals identified in the environment is growing exponentially.

**MO 296**
**Development of QSAR for soil toxicity of benzene-based compounds to Folsomia candida and validation of soil pore water concentration**
D Giesen[1], MTO Jonker[2], CMA Gestel[1]
[1]Vrije Universiteit Amsterdam, AMSTERDAM, The Netherlands
[2]IRAS, Utrecht University, UTRECHT, The Netherlands
The rapid development of industrial chemicals and the persistence of existing compounds in soils make it necessary to establish less time and resource consuming methods to determine possible toxic effects on soil organisms. Since the enormous improvements in computable software, quantitative structure activity relationships (QSARs) may provide an effective tool to overcome this challenge in bigger complexity. Toxicity to the springtail Folsomia candida was determined for nine chlorobenzenes, aniline, five chloroanilines and 5 chlorophenols, applying ISO guideline

11267. Toxicity in LUFA 2.2 and OECD artificial soils was compared, using reproduction as the endpoint. EC10 and EC50 were the chosen test parameters, with the focus on the EC50. In an attempt to develop a QSAR, toxicities were related to the Kow of the test compounds. Chlorobenzenes and chlorophenols showed a decrease in the effective concentration with increasing log Kow in nominal and modeled pore water concentration, respectively. In contrast the chloroaniline test series showed a decrease in toxicity in nominal concentration and an increase in toxicity in calculated pore water concentration with increasing log Kow. Based on the two calculated effective concentrations (EC10/EC50) a second experiment was designed to validate the pore water hypothesis, which described that only the freely available concentration in the pore water is causing toxic effects. For eight chlorobenzenes and 4 chloroanilines solid phase micro-extraction (nd- SPME) with polyacrylat coated fibers were used, to determine pore water concentrations at three time points over a four week standard toxicity test. The fibers were equilibrated over 4 weeks in soil - water suspension with 2 grams soil and 6 ml water. Subsequently, the fibers were extracted in cyclohexane and analyzed by GC-ECD. Only LUFA2.2 natural soil was used in the model confirmation experiment. The relative high volatility of the compounds leads already to high losses during the spiking and test preparation steps and a depletion of the total soil concentration before the actual test. The results indicate the losses of compounds during all steps of preparation and losses in the bioavailable fraction during test performance. However, the slopes of the regression models remained comparable. We therefore conclude that the pore water hypothesis is confirmed, but strongly advice to include pore water analysis for model validation in future experimental designs.

**Modeling ecotoxicity risks at the river basin scale: integration of the species sensitivity distribution (SSD) concept**

S Jesenská, S Némethová, K Brabec, L Bláha
Masaryk University, Research Centre for Toxic Compounds in the Environment, BRNO, Czech Republic

Traditional and simplistic approaches evaluate ecological risks of chemicals by calculating hazard indexes based on environmental concentrations and LOEC/NOEC values. Another methodology is using a concept of species sensitivity distributions (SSD), which has been traditionally used for predictive purposes, i.e. estimations of environmental quality criteria for e.g. pesticides (calculation of HC5 values). In the present study, we develop a model based on SSDs for retrospective assessment of ecotoxicological risks at the river basin scale. Existing ecotoxicological data were compiled for a number of priority chemicals (industrial chemicals, pesticides and their byproducts), that has been selected with respect to their relevancy in the model basins of the Zenne river (Netherland) and Odense river (Denmark). The ecotoxicity data were thoroughly assessed for their quality and resulting datasets served for calculation of SSD parameters of individual chemicals (mean and S.D. of the log-normal SSD). Integration of the SSD parameters with measured and/or modeled concentrations in the river basin is used to calculate PAF or msPAF values (potentially affected fraction or multisubstance PAF) for different temporal scales, which allow direct comparison of ecotoxicological risks at various localities within the investigated river basins. The outcomes of the model and its limitations will be discussed [Supported by the EU FP7 project AQUAREHAB and by the project CETOCOEN (no. CZ.1.05/2.1.00/01.0001) from the European Regional Development Fund].

**Acute toxicity to Daphnia magna test: comparison of predicted vs Actual EC50 results**

HS Vryenhoef, C Mead, J Handley
Harlan Laboratories Ltd., DERBYSHIRE, United Kingdom

With the implementation of REACH, the use of QSAR's to predict various ecotoxicological properties of chemicals is widely recognised. The results obtained from Acute Toxicity to Daphnia magna Tests are of importance for the risk assessment and labelling of chemicals, and hence this endpoint has been selected for the purpose of this comparison study.
The suitability of the program was assessed by comparing predicted values against experimental results obtained from regulatory testing of new and existing chemicals.

**MO 299**

**Evaluation of test methods for measuring toxicity to sediment organisms**

A Koelmans[1], GHP Arts[2], PJ van den Brink[2], TCM Brock[2], MJ van den Heuvel-Greve[3], J Schobben[3], H Smidt[1], NJ Diepens[4]
[1]Wageningen University, WAGENINGEN, The Netherlands
[2]Alterra, WAGENINGEN, The Netherlands
[3]IMARES, IJMUIDEN, The Netherlands
[4]Wageningen University and Research Centre, WAGENINGEN, The Netherlands

There are several internationally agreed tests available for investigating the potential long-term effects of substances, metabolites (or transformation products) and non-extractable residues on sediment-dwelling organisms. These standardised test methods focus on benthic invertebrates (e.g. *Chironomus, Lumbriculus*). However, as identified by CEFIC-LRI in their ECO17 call, there is a lack of methods for assessing potential effects on microorganisms, plants and animals from different taxonomic groups and for 'read across' from freshwater to marine sediment tests. The European Commission guidance for REACH identifies that specific effects of chemicals on plants and micro organisms are not covered by the currently available and regularly accepted test methods. Here, we provide a data- and model driven approach to improve the risk assessment for contaminants in sediments using (a) transparent protection goals, (b) underpinned model concepts how to link exposure and effects, (c) a single species test battery that covers appropriate focal species representative for different exposure pathways and sediment communities, (d) data from higher-tier experimental population and/or community studies, and (e) integrated state of the art exposure and population effect models, so that a tiered risk assessment scheme is achieved.

**MO 300**

**Toxic effects of nine polycyclic aromatic compounds on Enchytraeus crypticus in artificial soil in relation to their properties**

K Kobeticova[1], Z Simek[1], J Brezovsky[2], JH Hofman[1]
[1]Masaryk University, Research Centre for Toxic Compounds in the Environment, BRNO, Czech Republic
[2]Masaryk University, Loschmidt Laboratories, Department of Experimental Biology a, BRNO, Czech Republic

The aim of this study was to compare the toxic effects of selected two- and three-ringed PAHs and their N-heterocyclic analogues with one or two nitrogen atoms on the survival and reproduction of Enchytraeus crypticus in the artificial soil. If the toxicity was expressed as soil pore-water concentration (μmol/L), the toxicity showed clear pattern and dependency on structure and properties of the compounds. This was primarily related to the different lipophilicity of the compounds after that the toxicity significantly increased with increasing Kow value. This relationship indicates nonpolar narcosis as the general toxicity mechanism of the tested compounds. In addition, significant correlation of the ionization potential (IP) and toxicity of PACs has been identified by multidimensional QSAR models. The suggested importance of IP can help to explain deviations from proposed nonpolar narcosis model. Unraveled relationships between PACs structure and properties and their toxicity could help to the prediction of their effects in soil.

There are two interesting groups of organic compounds with very useful effects and which are said to be nontoxic. One group involves nootropics (or smart drugs), the other one perfluorinated aliphatic acids. Nootropics favourably affect a damage of central nerve system - cognitive ability and improve the activity of brain. They are used for memory or attention disorder. Their dosage is high, they are not metabolised and are totally excreted from the body. Their effect is explained by an increased supply of the brain by oxygen and nutrition and by eliminating free radicals. They should have no adverse or site effects. No severe consequences can be found by a literature survey, although some are sometimes mentioned. Possibility of nausea, a feeling a pressure in one´ s head, vomiting or allergic reactions are mentioned in a worst case. The global historical industry-wide emissions of total perfluorinated carboxylic acids were estimated to be thousands tonnes. It was estimated that the majority (about 80%) of perfluorinated carboxylic acids have been released to the environment from fluoropolymer manufacture and use. Their properties like negligible vapour pressure, solubility in water or bad degradability suggested that they would accumulate in surface waters. The estimated mass in various environmental compartments confirmed that surface waters, especially oceans, contain the majority of perfluorinated carboxylic acids implying a long environmental residence time. It was concluded that, in addition to atmospheric transport/degradation of precursors, ocean water transport could significantly contribute to their long-range transport even to Arctic region. The Tubifex assay predicts a chronic effect of perfluorinated carboxylic acids to aqueous organisms living in aqueous or muddy media even in low concentrations. Predictive expert system HAZARDEXPERT as a part of PALLAS (CompuDrug International Inc.) predicts actually no toxic effects of nootropics, but indicates a low, but not zero, probability of teratogenic effects. It evokes a question what consequences this fact may have for youngsters taking nootropics the whole life.

**Atom centred fragments (ACF) to estimate and decrease QSAR modelling uncertainties**

R Kühne[1], I Ebert[2], G Schüürmann[1]
[1]Helmholtz Centre for Environmental Research - UFZ, LEIPZIG, Germany
[2]Federal Environment Agency, Germany, DESSAU, Germany

Proper application of a QSAR models requires to consider the applicability and limitations of the model with respect to each individual case. In this context, the applicability domain of a model needs to be regarded.
However, even within the applicability domain the reliability of a single prediction is not obvious. The presented approach provides a mean to estimate the model uncertainty. With a validation set of compounds and their experimental values, model errors of similar compounds can be taken into account to estimate the prediction uncertainty for a test substance. The similar compounds are obtained from atom-centred fragments (ACF). The ACF method decomposes molecules into structural fragments consisting of a central atom and bonding neighbours. Similarity then is calculated by comparing the occurrences of the ACFs. Furthermore, the model errors for the similar compounds can be used to refine the model prediction.
The performance of the presented technique is shown with several examples for environmental partitioning and ecotoxicological endpoints. Several applications are implemented in the software system ChemProp.
Financial support by the European Commission through the project OSIRIS (Contract No. 037017) is gratefully acknowledged.

**MO 303**

**Chemical domain of QSAR models - extension to generic expressions**

R Kühne[1], B Wagner[2], G Schüürmann[1]
[1]Helmholtz Centre for Environmental Research - UFZ, LEIPZIG, Germany
[2]Eawag, DÜBENDORF, Switzerland

The chemical domain of estimation models can be characterised by an analysis of atom-centred fragments (ACF) from the training set. ACFs decompose molecules into individual atoms and their neighbourhood. The chemical domain of a test compound then is determined by examining the occurrences of the ACFs of this compound in the training set.
Basically, this approach is not restricted to estimation models, but can be applied to any compound set. The only requirement is the availability of all chemical structures. However, in real world applications this often is not the case. Data sets may include generic expressions as compound classes, mixtures of isomers, etc. An approach to overcome this limitation is presented for three important types of generalisation. These are variable alkyl substitutions, multiple occurrences of hetero atom fragments, and ring substitution patterns.
The study was funded by ERASM, Brussels. In addition, financial supported by the EU via the integrated project OSIRIS (contract No. 037017) is acknowledged.

**MO 304**

**Screening for new dioxin-like compounds with the classification SAR model**

P Urbaszek[1], M Haranczyk[2], T Puzyn[1]
[1]University of Gdansk, GDANSK, Poland
[2]Computational Research Division, Lawrence Berkeley National Laboratory, BERKELEY, United States of America

Dioxin-like compounds (DLs) is a subclass of persistent organic pollutants (POPs), showing

structural and toxicological similarities to 2,3,7,8-tetrachlorodibenzo-p-dioxin. Currently about 100 of toxic Dls have been identified. But taking into account that other policyclic hydrocarbons can exist as congeners and be substituted by Cl, Br or both, the total number of potentially toxic congeners is very large. Due to limited time and costs of laboratory tests, it is necessary to create screening methods that allow selecting those compounds, for which empirical research should be of the highest priority.
Thus, the aim of this study was to develop a novel classification method, capable to select those congeners (from 182 058 of theoretically possible brominated, chlorinated and mixed derivatives of 12 congeneric groups includes: acenaphthenes, anthracenes, biphenyls, biphenylenes, dibenzofurans, dibenzo-p-dioxins, dihydroanthracenes, fluorenes, naphthalenes, phenanthrenes, xanthenes, 9-fluorenones), which exhibit the same level of toxicity as 2,3,7,8-TCDD.
We generated chemical structures among the groups of compounds containing chlorine, and/or bromine. The structures were generated using ConGENER software. Next, we optimized geometries of the structures and calculated for them a set of 26 topological and quantum-mechanical descriptors (using semi-empirical PM6 method and DRAGON software respectively). Simultaneously, we collected all available experimental data on dioxin-like toxicity (toxic equivalence factors, TEFs, and relative effect potencies, REPs). Also empirically confirmed information about particular congeners which are not toxic were aded. We divided the collected data, into two classes: toxic (TEFs and/or REPs > 0.0001) and non-toxic. Compounds from both classes, were then utilized for training and external validation of the classification SAR model. The SAR model was developed with two chemometric methods: linear discriminant analysis (LDA) and k-nearest neighbor (kNN) non-linear classifier. The most optimal set of descriptors was selected with a genetic algorithm (GA). The best model has been developed for a set of 182 058 compounds, to found new dioxin-like compounds.

**MO 305**

**Exploring the QSARs for OH Tropospheric Degradation of VOCs using freely available online descriptors**

PP Roy, E Papa, P Gramatica
University of Insubria, VARESE, Italy

Tropospheric photochemical air pollution has impacts on scales ranging from local to global. The reactions of organic pollutants in the atmosphere with OH radicals, $NO_3$ radicals, and ozone are of great concern from an ecological standpoint for risk assessment measurement such as degradation pathways, atmospheric lifetimes and fate of these compounds. It was already established that reactions with hydroxyl radical (-OH) is the most important pathway of day time removal of organic pollutant in atmosphere because of the reactive nature of OH radical to react practically almost with every volatile organic compounds (VOCs) in the troposphere. Due to limited availability of experimental gas phase rate constant data for chemicals, alternative theoretical approaches like QSAR/QSPRs are often practiced to predict the high risk of organic chemicals and to reduce the time consuming, expensive and difficult experimental procedures.
In this study we developed QSAR models for hydroxyl radical tropospheric degradation rate of 460 VOCs, using HOMO, LUMO from Hyperchem minimization in addition to separately freely available online molecular descriptors (from the CADASTER online platform- www.cadaster.eu) or descriptors calculated from an updated version of DRAGON software. The Genetic Algorithm as Variable Subset Selection (GA-VSS) was used to select the relevant molecular descriptors in the modeling step (Ordinary Least Squares (OLS) regression). Three splitting criteria [K-ANN, k-means cluster and random on response] were applied for verifying the external predictivity of developed QSAR models, with special emphasis on model applicability domain which was verified by the leverage approach. The statistical qualities of the models developed from the pool of online descriptors were comparable with those obtained from the DRAGON descriptors and, most importantly, the GA selected, in addition to HOMO, descriptors with comparable mechanistic meaning, from completely different pool of input descriptors.
So it can be suggested to use online freely available descriptors to increase the reproducibility of the models for the safety of environment and for REACH.

**MO 306**

**On the agreement of external validation parameters for linear regression QSAR models**

N Chirico, E Papa, P Gramatica
Università degli studi dell'Insubria, VARESE, Italy

The evaluation of linear regression QSAR models performances, both in fitting and external prediction, is of pivotal importance. While leave-one-out (LOO) $Q^2$ internal validation technique (cross-validation) is well established, different external validation parameters have been proposed in the last decade: $Q^2$-F1 (Shi), $Q^2$-F2 (Schuurmann), $Q^2$-F3 (Todeschini), $r^2m$ (Roy) and the Tropsha-Golbraikh method. These parameters usually are in accordance, making one confident of a model predictivity, but doubts arise when they give contradictory results. In these cases the QSAR model developer should understand which one of the aforementioned parameters is "the best". However this is not an easy task, mainly because no one of these parameters could be considered "the best"in every situation. We are thus looking for a simpler method to evaluate the external predictivity of the models, independently on the set composition. In our opinion, the simplest method consists in the quantification of the similarity among the experimental data of external test set versus the corresponding values calculated by the model. In this study our new method has been used as a reference and we have evaluated the number of contradictory and agreeing results on validation parameters by means of 210.000 simulated datasets. A wide range of possible scenarios has been generated and, concerning the more realistic ones, 95% of agreement has been found among our method and all the aforementioned validation parameters together. Our proposed method is the most precautionary among those analyzed. We have verified that disagreements among results is related to two possible situations: a) the external data points are well predicted (good matching), while at least one of the validation parameters rejects the model (rare), b) the matching is not good and one or more validation parameters accept the model (less rare). The second alternative is more dangerous for QSAR models, thus a deeper analysis of the results is suggested. Our method, verified also on real models, has been proposed as a tool to be used in addition to the aforementioned external validation parameters to find out this kind of critical models with doubtful predictivity.

The implementation of the EU legislation concerning the registration, evaluation, authorization and restriction of chemicals (REACH) requires demonstration of the safe manufacture of chemicals and their safe use throughout the supply chain. REACH encourages development of new in vitro test methods and replacement of animal tests wherever possible by alternative methods. These goals are not achievable without well-trained personnel with a broad expertise and knowledge in both experimental and computational areas of environmental sciences. The requirements for such scientists, however, are not limited to the REACH implementation itself. Large companies and SMEs could be interested to employ such specialists to perform risk assessment and prioritization of molecules in the development stage. Therefore, the primary objective of the Environmental Chemoinformatics Marie Curie Initial Training Network (http://www.eco-itn.eu MC ITN ECO) is to contribute to the education of a new generation of scientists, environmental chemoinformaticians, who will receive advanced training in both environmental and computational methods. To achieve this goal the ECO is educating its fellows using expertise and knowledge of its partners in various complementary computational and experimental areas of environmental sciences. The additional training is offered by means of Winter and Summer Schools and includes both theoretical and practical courses. The internships to the laboratories of associated partners allows fellows to learn new methods and to broaden their knowledge in the field. Currently, ECO employs 10 long-term fellows working towards their PhD in laboratories of partners. The ECO also offers a flexible system of more than 30 Short Term Fellowships to Early Stage Researchers who are invited to apply and can stay in laboratories of partners from 3 to 12 months (see http://www.eco-itn.eu/positions ). The experience with recruitment of fellows as well as direction of outgoing studies in environmental chemoinformatics within the project will be presented.

**MO 308**

**ANTARES project: an evaluation of non testing methods for REACH**

C Milan[1], E Benfenati[1], A Roncaglioni[1], S Alivernini[2], R Knauf[3], G Gini[4], F Lemke[5]
[1]Institute for Pharmaceutical Research "Mario Negri", MILAN, Italy
[2]Istituto Superiore di Sanità, ROME, Italy
[3]Federazione Nazionale dell'Industria Chimica, MILAN, Italy
[4]Electronic and Information Department, Politecnico di Milano, MILAN, Italy
[5]KnowledgeMiner Software Frank Lemke, PANKETAL, Germany

Animal testing in Europe is expected to increase for the activities related to the REACH legislation. Currently in Europe a lot of animals are used per year for laboratory experiments.
To correctly evaluate the impact on the environment and human health, industry will pay a high cost (billions of euros), millions of animals will be killed, and it is questionable if the number of laboratories is sufficient to cope in a reasonable time with the need to produce the toxicity data.
To solve all these problems, the REACH legislation promotes the use of non-testing methods (NTM).
The term NTM refers to all the approaches used to predict the effects of chemical compounds without the use of the real chemical compound, but on the basis of the chemical structure only and comprises a series of different tools whose commonality lies in the identification of a relation between chemical structure and exhibited activity or toxicity.
There are different types of NTM to assess activity and/or toxicity of chemicals, among them Quantitative structure-activity relationship (QSAR) methods are the most used. QSAR is the process by which chemical structure is quantitatively correlated with a well defined process, such as biological activity or chemical reactivity.
In this context a LIFE project, named ANTARES, has been funded to evaluate existing NTM and their feasibility for REACH purposes.
As the project has the main target to analyze the use of NTM in accordance to REACH, and to identify suitable method, the first step has been to identify relevant criteria for comparing QSAR methods.
A list of them has been established. They have been divided into main (more important) and additional criteria. For each of them a particular score has been decided based on the importance of the criterion.
Using the overall score we will first identify available QSAR models which could be used for REACH. Then, if there are more than one method for the same endpoint, we will rank them, using the proposal scoring system.
The availability of checked and validated non-testing methods will provide a huge, immediate benefit, producing new important knowledge, abating the costs and time needed to get the information on chemicals, and saving animals. The introduction of these methods will reduce the use of animal tests not only for their use by chemical industry, but in the other sectors too.
Financial support from ANTARES project (LIFE 08 ENV/IT/000435) is gratefully acknowledged.

**MO 309**

**MISTEX: A web-interfaced database to standardize and facilitate data collection, storage and cross requests in ecotoxicology**

PA Biron, C Deschamps, E Billoir, ML Delignette-Muller, S Charles
University of Lyon, VILLEURBANNE CEDEX, France

Today, global change and accelerated xenobiotics production play active roles in the rising contamination risk of ecosystems and subsequently of human health. The ecosystem answer to such environmental perturbations (physical, chemical and/or biological) is studied in all compartments of the biosphere (air, soil and water) and at all levels of biological organization. Depending on the level of biological organization, answer may strongly differ, with major changes in terms of biochemistry and physiology, of life history traits (survival, growth, reproduction), of demography, or of structure and functioning, at the cell, individual, population or ecosystem levels, respectively. Concomitantly, exponentially increasing amounts of data are collected, which may concern any kind of species, toxic compounds, life traits and environmental conditions. The need for a unifying database is then become crucial in order to standardize the way theses data are collected and stored, and to facilitate cross requests in view of meta-analyses.
The relational database MISTEX (Modelling, Inference and Simulation for Toxicological Evaluation of Xenobiotics) was imagined to meet such requirements, grouping together raw data from any kind of experiment in a consistent way and keeping intact the context in which they have been acquired. At present, MISTEX stores measurements as raw data (number of survivors, length[3DOTS]) associated with all meta-data that allow their unique identification (geolocation, species, compound[3DOTS]). MISTEX works through a Web interface, which provides among others a data capture sheet to collect them in a standard way and directly send them to

the database. From MISTEX, simple or cross requests can be done, for example to gather all data on a particular species or a particular trait whatever the studied compound. This will later allow one to combine its own data with other information resources, to design further complementary experiments, to elicit prior probability distributions in view of Bayesian inference, or to validate predictions with dynamical mechanistic models.
Its flexibility, its genericity, its user-friendly nature and its evolvability make MISTEX apart from other existing databases. Works are currently in progress to couple MISTEX with R packages - some of them already exist (lattice, drc), some others are to be thought up - in order to directly link shared data with graphical viewing, statistical analysing and mechanistic dynamical modelling tools.

## PE02 - PBPK modelling in ecological risk assessment

### MO 312

**Using bird and mammal body burden modelling in pesticide risk assessments: a regulatory perspective**

AC Brooks[1], R Sharp[1], M Fryer[1], R Kittoe[1], M Reed[1], M Percival[1], S Fryday[2], H Thompson[2]
[1]Health and Safety Executive, YORK, United Kingdom
[2]Food and Environment Research Agency (FERA), YORK, United Kingdom

The current EU initial assessment of the acute risk to birds and mammals exposed to pesticides in plant protection products involves derivation of a risk quotient based on acute toxicity data (LD50) and theoretical estimation of exposure in daily dietary intake. The acute risk assessment can be refined by taking account of physiological processes (e.g. absorption, elimination) and ecological factors (e.g. feeding rate). Body burden models, such as EFSA (2005)[1], attempt to address such issues, calculating the time taken to achieve a lethal dose and comparing this to the time taken to induce cessation of feeding. Such models are potentially useful in acute risk assessments given that the options for refinement are limited. However, there are many uncertainties in using the models from a regulatory perspective. Selection of an appropriately robust model is the first challenge as model validation is limited by a lack of relevant field data. The validation process is also problematic due to imperfect information on the exact conditions (e.g. feeding rate) that lead to mortality and (likely) lack of availability of input parameters for the species involved. The applicability of the models for different types of chemicals and modes of action is also uncertain. Perhaps the most challenging stage though is the selection of parameters with which to populate the models. These must be derived from studies that are not designed to produce such data. It also often involves extrapolation of data between birds and mammals, with limited information regarding relevance. There are also complications when attempting to increase the ecological relevance of the models e.g. incorporating mixed diets. The final stage of predicting acceptable risks is consequently problematic, with many interpretations being possible depending upon whether best-case or worst-case parameters are used. The aim of this poster is to present some of the uncertainties associated with this approach with the aid of case studies. We highlight areas where future research could be focused to enable these models to be used with more confidence within risk assessments and ensure protection goals are being met.

**Avian blood sampling for toxicokinetic modelling using dried blood spots (dbs)**

T Frey, JB Beavers
Wildlife International, Ltd., EASTON, United States of America

Physiologically-based pharmacokinetic (PBPK) models have been used by the pharmaceutical industry for many years in drug development, typically using mice and rats as test subjects. Improvements in analytical instrumentation and dried-blood spot (DBS) sampling techniques have reduced the volume of blood needed per sample. Typically 60 -100 µl need to be collected for a triplicate DSB sample (~15 µl per spot). For northern bobwhite (Colinus virginianus) that volume is considerably below the generally recommended limit for blood sample size of 1% of the bird's body weight. The DBS method of blood collection has also simplified the handling and processing of the samples prior to analysis. Therefore, study designs could be modified to take advantage of these improvements. Smaller blood volumes allow for decreases in the time interval between sampling events for an individual animal or, in the case where only a single sample was taken from an animal, multiple samples could now be collected. This would result in a reduction in the number of animals used.
However, anatomical and physiological differences between birds and mammals needed to be considered when developing techniques for collecting the blood samples for ecotoxicological studies with bird species. Collection methods considered were toe clipping, and venipuncture using a lancet, and using a needle and syringe. Sites for venipuncture included the jugular veins and the wing veins (cutaneous ulnar vein, also known as the brachial).
Toenail clipping for avian blood sampling is generally considered a painful technique and a sample could potentially be contaminated if the test substance is presented through the diet. Toenail cuts tended to bleed slowly and clotting was a problem. Lancing a wing vein also had similar problems with slow bleeding, clotting and the potential for contamination. Using a needle and syringe for blood collection and rotating the collection sites among the jugular and wing veins, left and right sides for both, was the preferred technique for collecting the necessary blood volume. This poster presents more a more detailed description of the procedure.

### MO 314

**Toxicokinetic of perfluorooctane sulfonate (PFOS) following oral exposure under realistic dose. Implication for bioaccumulation assessment. Preliminary study with rabits.**

E Alonso[1], M San Andrés[2], C Rodriguez[2], JJ de Lucas[2], MA Martinez[1], M Saez[3], B Jiménez[3], JV Tarazona[4]
[1]CIEMAT, MADRID, Spain
[2]Toxicology and Pharmacology Department. Veterinary UCM, MADRID, Spain
[3]CSIC, MADRID, Spain
[4]INIA, MADRID, Spain

The bioaccumulation of chemicals in biota and the potential for biomagnification through the food chain represent essential elements for a proper environmental risk assessment. Toxicokinetic approaches have been increasingly employed to estimate final concentration of chemicals on top predators and hence to asses the potential biomagnification. This kind of studies comes from the simplistic lipophylic-equilibrium theory allowing to investigate other chemicals with different patterns of accumulation. That is the case of perfluorinated compounds (PFCs) which are preferentially bound to proteins and retained in the blood and liver of animals. However, pharmacokinetic studies with PFC in mammals are limited and mostly carried out at relatively high doses. Consequently, the first objective of this study was to characterize the toxicokinetic of a PFC; concretely perfluorooctane sulfonate (PFOS) in rabbits (Oryctolagus cuniculus) as representative mammal. Also, the oral exposure to PFOS was conducted under realistic chronic dose (0.1 µg/kg at day). Rabbits were fed with PFOS-contaminated food by gastric intubation during three months for assessing their uptake. Subsequently the contaminated food was eliminated and the assay continued during other three months for covering the depuration period. All through the experiment 2mL of blood were sampled weekly and PFOS was analysed. From the experiment, the toxicokinetic of PFOS have been estimated obtaining elimination blood rate of 76.25 ± day -1. The toxicokinetic parameters were included into a previously developed biomagnification model. This model was designed to estimate daily chemical concentrations covering the possible processes taking place within this period of time (uptake, distribution and elimination of chemical). The calibration study with PFOS toxicokinetic parameters demonstrated the capacity of biomagnification model to produce proper estimations of expected concentrations. Therefore, this model could be considered as a useful tool for chemical risk assessments.

**Toxicodynamic experiment for different time-variable exposure regimes of the insecticide chlorpyrifos on aquatic arthropods**

MI Zafar[1], NJ Diepens[2], MN Rubach[1], PJ van den Brink[1]
[1]Wageningen University and Alterra Research Centre, WAGENINGEN, The Netherlands
[2]Wageningen University and Research Centre, WAGENINGEN, The Netherlands

Non-target organisms may be exposed to fluctuating concentrations or sequential pulses of pesticide contaminants. Currently, evaluation of the potential adverse effects of pulsed pesticide exposure on non-target aquatic organisms is considered as a major challenge. The Threshold Damage Model (TDM) is a process -based model to predict the acute effects of pulsed pesticide exposure on the survival of aquatic invertebrates and consists of a toxicokinetic part in which uptake and elimination are described and of a toxicodynamic part including processes such as damage and recovery. In the latter step, internal thresholds are compared with hazard values and then translated into survival. The model assumes stochastic death. Here we present data from a Toxicodynamic experiment (TD) in the laboratory with the model substance chlorpyrifos. The survival experiment is designed to (1) get information about faunal responses to time variable exposures and how species may differ in sensitivity (2) parameterize the toxicodynamics part of the TDM for different species on basis of the two endpoints mortality and immobilization. Toxicodynamic experiment quantified survival of Cloeon dipterum and Chaoborus obscuripes to varying patterns of chlorpyrifos exposure over 34 and 31 days, respectively. The toxicodynamic parameter values for the killing rate constant (kk), recovery rate constant (kr), the threshold and background mortality were estimated by fitting the TDM with the experimental observed survival data per species. This was done with the least-squares method based on Levenberg-Marquardt algorithm implemented in the program Open Model v1.2 . *C. obscuripes* showed a delayed effect in immobility and mortality without any recovery where as *C. dipterum* responded directly to the exposure and some recovery occurred within 2 to 6 days. In general, the effect of the pulses became less when more time was given for elimination and potential recovery, as was intended by the experimental design. The TDM was able to predict the experimental data well ($R^2$: 0.94 and 0.91 for *C. obscuripes* and *C. dipterum,* respectively*)* however, not all parameters were robust e.g. the threshold parameter.

### MO 317

**Toxicokinetic-toxicodynamic (TKTD) modelling of survival of Gammarus pulex following exposure to multiple pulses of the fungicide propiconazole**

AM Ruotsalainen, K Schirmer, R Ashauer
Eawag, Swiss Federal Institute of Aquatic Science and Technology, DÜBENDORF, Switzerland

In aquatic environments, toxicant concentrations fluctuate over time. The risks they pose to organisms are currently evaluated by comparing time-weighed averages (TWA) of observed concentrations to short term toxicity data. However, in multiple pulse exposures both elimination of compounds and organism recovery between pulses play a role in the effects of subsequent contaminant pulses. The current study aims to predict survival following multiple pulse exposures using toxicokinetic-toxicodynamic (TKTD) models with differing assumptions of survival: an individual tolerance distribution (IT) and stochastic death (SD).

A short term toxicity test, toxicokinetic (TK) experiments and a long term pulse toxicity test were conducted with the aquatic invertebrate *Gammarus pulex* exposed to the fungicide propiconazole. The pulse toxicity test included treatments with two pulses and different recovery intervals in between and one constant exposure treatment with the corresponding TWA concentration calculated from the pulse treatments. TKTD models assuming IT and SD were fitted to the survival data and the goodness-of-fits were compared. In addition, the goodness-of-fits when simulated internal concentrations based on TK test were included or excluded were compared. Also, the models were fitted to short term toxicity data and it was tested how well they predict the effects in multiple pulse exposure.
The results show that propiconazole is eliminated fast from *G. pulex*. In addition, two possible metabolites were observed; however, the concentrations remained low which indicates that they were either formed very slowly or eliminated very fast. The long term toxicity test showed that survival at the end of the experiment was higher in treatment with TWA concentration when compared to pulse treatments. Based on the TKTD model, toxicodynamic processes were slower than the elimination of propiconazole, i.e. recovery from damage was the dominant recovery process. Altogether, the survival was better characterised by the model assuming individual tolerance in the *G. pulex* population. The IT model with and without simulated internal concentrations estimated similar overall recovery. This indicates that the TK test was not necessary when predicting the survival.

**A TK/TD model for sublethal effects on Myriophyllum spicatum**

S Heine[1], W Schmitt[2], C Banman[2], D Belgers[3], P van den Brink[3]
[1]University of Trier, TRIER, Germany
[2]Bayer CropScience, MONHEIM, Germany
[3]Alterra, WAGENINGEN, The Netherlands

Ecological models, particularly TK/TD models, are capable to refine risk assessments for plant protection products. In this work a previously published growth model for Myriophyllum spicatum was extended to a TK/TD model by integrating respective toxicokinetic and toxicodynamic parts. Uptake and distribution kinetics are modeled by physicochemical properties of the substance tested and species-specific parameters. These species-specific parameters are derived from published literature. The toxicodynamic sub model describes the reduction of growth rates based on internal concentrations and $EC_{50}$ values of the investigated chemicals.
First comparisons between experimental laboratory data for growth inhibition under different exposure scenarios (static and short term) and calculated growth curves demonstrate that the model can simulate reversible growth reduction in Myriophyllum spicatum properly. An extrapolation to effects under field conditions is possible by considering realistic climate and environmental conditions. The ability to use arbitrary exposure patterns as an input for the toxicokinetic sub model enables a realistic risk assessment for plant protection products taking into account specific predicted environmental concentrations in surface water.

**MO 319**

**Mechanistic modelling for risk assessment of cadmium and silver toxicities on abalone populations**

WY Chen[1], YR Ju[1], BC Chen[2], JW Tsai[3], CJ Lin[1], CM Liao[1]
[1]National Taiwan University, TAIPEI, Taiwan
[2]MingDao University, CHANGHUA, Taiwan
[3]China Medical University, TAICHUNG, Taiwan

The purpose of this study was to link toxicokinetics/toxicodynamics and subcellular partitioning for assessing the susceptibility and growth inhibition risks of abalone Haliotis diversicolor supertexta exposed to waterborne and foodborne cadmium (Cd) and silver (Ag). We reanalyzed the published data on growth inhibition and subcellular partitioning associated with the present mechanistic model to explore the correlations among elimination ($k_e$), detoxification ($k_d$), and recovery ($k_r$) rate constants and to assess the growth inhibition risk. We found a positive correlation among $k_e$, $k_d$, and $k_r$ in abalone exposed to Ag. We also employed a life-stage based probabilistic assessment model to estimate the growth inhibition risk of abalone to environmentally relevant Cd (5 - 995 $\mu g\ L^{-1}$) and Ag (0.05 - 9.95 $\mu g\ L^{-1}$) concentrations in Taiwan, respectively. The results showed that abalone had a minimum 20% probability of growth inhibition risk exposed to Cd, whereas Ag exposure was not likely to pose the risk. When abalone population exposed to the same Cd and Ag concentrations, the Cd- and Ag-exposed maximum biomasses were estimated to be 0.0039 and 0.0038, 61.61 and 43.87, and 98.88 and 62.97 g for larva, juvenile, and adult, respectively. Our study offers a useful tool to detect the potential growth biomass of abalone populations subjected to Cd and Ag stresses and also provides mechanistic implications for a long-term ecotoxicological risk assessment in the realistic situations.

**MO 320**

**Predicting internal concentrations of chemicals in fish based on PBPK and one-compartment models**

J Stadnicka, K Schirmer, R Ashauer
Eawag, Swiss Federal Institute of Aquatic Science and Technology, DÜBENDORF, Switzerland

European Union regulations require comprehensive testing and risk assessment before a chemical might be approved for use. In ecological risk assessment of chemicals in water, fish play a very important role, being the only vertebrate representative in freshwater systems. For this reason it would be very useful to simulate the relationship between external and internal dose in fish, and to define internal dose of a chemical using toxicokinetic modelling. Thus far, quantification of chemical toxicity is generally based on measurements of external exposure; however, in order to understand and interpret toxicological effects well, using internal concentrations of chemicals is more suitable. The goal of this study was to predict internal concentrations in fish based on the hypothesis that physiologically based pharmacokinetic models simulate internal concentrations of chemicals in better agreement with measured data (in fish tissues and whole body) than one-compartment approaches. To achieve that aim, two one-compartment models and one physiologically based multi-compartment model (PBPK) were used in order to simulate internal concentrations of chemicals in fish and fish tissues. Only respiratory uptake routes were considered for both model types and were described by mass-balance differential equations. Toxicokinetic models were compared with measured data of chemical internal concentrations in rainbow trout and fathead minnow. These two fish species were chosen because of their wide application in toxicity testing and the availability of their physiological parameters.
For internal concentrations of chemicals both in fish tissues and in whole body, the PBPK model outperformed one-compartment models; however for rainbow trout, agreement between each of the model and measured data was higher than for fathead minnow.

**Health risk assessment of a PFOS and PFOA mixture by using a whole body pharmacokinetic model**

F Fàbrega, M Mari, M Nadal, M Schuhmacher, JL Domingo
Universitat Rovira i Virgili, TARRAGONA, Spain

Despite their increasing use in human health risk assessment, the application of physiologically-based pharmacokinetic (PBPK) models for the characterization of chemical mixtures is still incipient. Notwithstanding, humans are exposed to multiple substances rather than to individual chemicals. The purpose of the present study was to develop a single-compartmental PBPK model with the capacity to integrate chemical pollutants with different physical-chemical and toxicological properties. The model was applied in a specific case-study: the cumulative exposure of perfluorooctanesulfonic acid (PFOS) and perfluorooctanoic acid (PFOA) through dietary intake and water consumption, the most predominant routes of exposure. While PFOS was listed under the Stockholm Convention in May 2009, PFOA is a serious candidate to enter that list. In recent years, the concentrations of these as well as other perfluorinated compounds have been analyzed in environmental (water), biological (blood) and food samples collected in Catalonia (NE of Spain), as part of a large monitoring investigation to trace the predominant sources of exposure. The PBPK model here developed was validated by comparing theoretical values with experimental data on PFOS and PFOA levels in drinking water, foodstuffs and blood.

**General unified theory of survival - a toxicokinetic-toxicodynamic framework for ecotoxicology**

T Jager[1], C Albert[2], T Preuss[3], R Ashauer[2]
[1]Vrije Universiteit, AMSTERDAM, The Netherlands
[2]Eawag, DUEBENDORF, Switzerland
[3]RWTH Aachen University, AACHEN, Germany

Toxicokinetic-toxicodynamic models (TKTD models) simulate the time-course of processes linking exposure concentrations to toxic effects on organisms. Unfortunately, even for an apparently simple endpoint like survival, a large number of very different TKTD approaches exist. Examples are the critical body residue (CBR) approach, the critical target occupation (CTO) approach, the damage assessment model (DAM), the DEBtox model for survival, and the threshold damage model (TDM). These differ in their underlying hypotheses and assumptions, although these are usually not explicitly stated. To clarify the underlying assumptions of the various modelling approaches, and to show how they relate to each other, we developed a "General Unified Theory for Survival"(GUTS). From GUTS, a large range of existing TKTD models for survival can be derived as special cases, but also mixed models may result. For example, GUTS can take on the extreme philosophies of the CBR models (immediate death and a distributed threshold in the population) and hazard models (death is stochastic at the level of the individual), but also a combination of these two extremes (stochastic death with a distributed threshold). We envision that GUTS will help to increase the application of TKTD models in ecotoxicological research as well as environmental risk assessment of chemicals. It unifies a wide range of apparently unrelated approaches, clarifies their underlying assumptions, and facilitates further improvement in the modelling of survival under chemical (and other) stress.

**An algal toxicokinetic model for population level ecological risk assessment**

T Nagai[1], S Ishihara[2], A Yokoyama[1], T Iwafune[2]
[1]National Institute for Agro-Environmental Sciences, TSUKUBA, Japan
[2]Food and Agricultural Materials Inspection Center, KODAIRA, Japan

Various herbicides are used for weed prevention in paddy fields. These herbicides flow directly out from paddy fields to rivers through drainage channels, and are detected from April to August in river waters in Japan. Moreover. these herbicides are highly toxic to algae, and therefore there is a higher concern for the aquatic risk caused by paddy herbicides. Population viability is a main endpoint of ecosystem protection, and therefore it is needed to assess timed effect and subsequent population recovery considering these time-varying exposure. The aim of this study is the development of an algal toxicokinetic model to predict algal population dynamics under time-varying herbicide exposure for population level ecological risk assessment.
We investigated the effect of herbicide pretilachlor, which is widely used in paddy fields in Japan, on the growth and mortality of the green algae Pseudokirchneriella subcapitata. According to the standardized test guideline, a 72 h algal growth inhibition test was conducted. Dead cells in subsamples were stained with the green nucleic acid dye SYTOX-Green, and live and dead cells were counted separately using flow cytometry. Moreover, cells in the algal growth inhibition test that were exposed for 72 h were inoculated with herbicide-free fresh medium, and their growth was monitored to investigate population recovery after timed exposure. Algal population dynamics are described based on the logistic model and toxicity are described by growth inhibition and mortality. Model parameters were deterimned from these test results, and model prediction of algal population dynamics was consistent with the measured values.

**MO 324**

**Prediction of the blood/air and fat/air partition coefficients from chemical structure**

S Stöckl, R Kühne, RU Ebert, G Schüürmann
Helmholtz Centre for Environmental Research - UFZ, LEIPZIG, Germany

For physiologically based pharmacokinetic (PBPK) modelling, partition coefficients between tissues and environmental compartments are required. Two important parameters are the distribution of organic chemicals in the blood/air and fat/air system. Available human and rat data have been collected from various literature sources and evaluated. The number of available data is rather limited, yielding a set of experimental blood/air partition coefficients for 279 compounds, fat/air data for 124 compounds only.
The data sets have been employed to develop new estimation models for these properties at body temperature. The models are superior to existing literature approaches based on Abraham-type linear solvation energy relationships (LSER). The new models estimate the blood/air and fat/air partitioning through two different descriptors. The model performances depend on the descriptor quality. They yield squared correlation coefficients of regression of $r^2 = 0.88$ and 0.90, respectively.
The study was supported by the EU projects 2-FUN (contract No. 036976) and OSIRIS (IP, contract No. 037017).

## RA02 - Aquatic and terrestrial mesocosm and field studies - Messages from complex systems to academia, regulators, and industry

**Lab-to-field assessment factor evaluation for the nickel surface water pnec**

A Fairbrother[1], DK Deforest[2]
[1]Exponent, BELLEVUE, United States of America
[2]Windward Environmental, SEATTLE, United States of America

To develop chemical benchmarks that are protective of natural systems, regulators must account for the unknowns involved when extrapolating information from a few test species in simple laboratory environments to the complexity of natural ecosystems. In this paper, we examine the sources of uncertainty associated with the predicted no effects concentration (PNEC) for nickel (Ni) in surface water. In the European Union risk assessment for Ni (ECB 2008), the PNEC for surface water is derived from the HC5 calculated as the 5th percentile of the species sensitivity distribution (SSD) based on chronic EC10/NOEC values for 31 species divided by an assessment factor (AF) of 2. Because the HC5 is derived using the Biotic Ligand Model (BLM), it also accounts for site-specific bioavailability. In a 4-month mesocosm study (Fraunhofer 2010), the BLM-based Ni HC5 value, based on the chemistry of the mesocosm test water, was 3.5 to 5.7-fold lower than the multispecies NOEC. Accordingly, an additional AF would not be required for the HC5 to be protective of the community NOEC. In a field study in the UK (WCA Environment 2009), ambient Ni concentrations relative to population- and community-based benthic macroinvertebrate indices indicated that deterioration in ecological quality is unlikely to occur at the HC5 Ni concentration. Of 632 sites in the Forum of European Geological Surveys (FOREGs) database where Ni concentrations were measured, and where corresponding dissolved organic carbon, pH, and hardness measurements were within the calibration range of the Ni BLM, just 1% had an ambient Ni concentration exceeding the HC5, while 7% had ambient Ni concentrations exceeding the HC5 divided by two. De Vries et al. (2010) concluded that the HC5 level, for any chemical stressor, is a protective threshold for changes in biodiversity, as defined by species richness and heterogeneity, and noted that changes in concentrations at and below the HC5 would not be detectable. Given the resilience of ecosystem function, coupled with the protectiveness of the Ni HC5 when compared to mesocosm- and field-based effects data, we conclude that the uncertainty within the aquatic effects assessment is sufficiently understood, and that the HC5 provides an adequate level of protection for freshwater systems.

**MO 328**

**How mine drainage waters affect lotic systems: results from a Triad-based Environmental Risk Assessment of a disused mining area in Tuscany (Italy)**

A Viarengo[1], T Bo[1], A Copetta[1], A Dagnino[1], L Oliveri[1], S Sforzini[1], S Terrana[2], L Zaninetta[2]
[1]Università del Piemonte Orientale, ALESSANDRIA, Italy
[2]Syndial S.p.A., SAN DONATO MILANESE (MI), Italy

Aim of this study was to determine the potential environmental impact posed to a lotic system by effluents from a disused mining area in Tuscany (Italy). To analyze the impact of mine drainage water inputs, a Triad-based Ecological Risk Assessment, encompassing chemistry, ecotoxicology and ecology, was carried out along a small water-body, up and downstream the confluence with the channel collecting mine waters.

Chemical analyses were focused on determining metals and inorganic contaminants concentration in water. Water toxicity was evaluated utilizing different model organisms, i.e. bacteria, algae, protozoa, crustaceans. Sediment toxicity was determined testing interstitial water with protozoa and nematodes, and bulk sediment with seeds and ostracods. Finally, the benthic macroinvertebrate community structure was analyzed as ecological endpoint.

The elements of interest in the mine waters of the study area are iron, manganese and sulphates: although a gradient in chemical concentrations was observable between the up- and downstream sites, levels were below safety thresholds in both sites. Only mild toxic effects were detected on protozoa after exposure to superficial and interstitial water and on seeds exposed to bulk sediments; no alteration was evident in genotoxicity endpoints on the two model organisms, i.e. protozoa and seeds. Interestingly, benthic macroinvertebrate community showed a similar structure in both up- and down-stream sites; surprisingly, a significant reduction of benthic diversity with respect to the stream collecting mine effluents was detected both in the up- and downstream sites. The integration of the Triad data into an environmental risk index (EnvRI) applying an Expert Decision Support System shows a low level of risk, below the safety threshold (0.25), due to the mine effluent inputs (EnvRI= 0.15). Pollutant sources in areas upstream the study sites seem to contribute to the degradation of the lotic system, reducing the biological quality of the stream. In fact, higher values of EnvRI are obtained for both the up- and downstream sites (respectively 0.30 and 0.31) when considering a third unpolluted reference point in the mine area. A risk of biodiversity decline in the study area is evident, even if it is not related to the mine drainage input. In fact, the high biodiversity of the macroinvertebrate community structure (EBI= 10) in the stream collecting mine drainage waters suggests low bioavailability of pollutants for the biota.

**MO 329**

**Estimating safe concentrations of four heavy metals (Cu, Zn, Cd, and Mn) from field effects on species richness of riverine macroinvertebrates**

Y Iwasaki[1], SJ Ormerod[2]
[1]Tokyo Institute of Technology, TOKYO, Japan
[2]Cardiff University, CARDIFF, United Kingdom

The ecological impacts of heavy-metal contamination on aquatic ecosystems are a major concern worldwide. Ecological risk assessment is thus necessary for effective risk managements. In this context, the estimation of the safe concentrations (SCs), such as predicted no effect concentration (PNEC) and environmental water quality criteria, at which unacceptable effects are most likely to be avoided, is critical. Although such concentrations are usually determined from laboratory toxicity tests to assess effects on individual-level traits, the real goals of ecological risk management are to protect populations, communities, and ecosystems in the natural environment. Information on metal-induced field effects can therefore provide useful insights into the SCs in the natural systems. Despite previous studies evaluating the effects of heavy metals on aquatic organisms, knowledge useful for estimating the safe concentrations is limited.

We estimated SCs of heavy metals (copper, zinc, cadmium, and manganese) from macroinvertebrate survey data collected from over 400 individual sites in UK, US, and Japan. Benthic macroinvertebrates are widely used to evaluate the anthropogenic impacts on freshwaters, and we used EPT (Ephemeroptera, Plecoptera, and Trichoptera) richness as a metric in this study. The relationship between dissolved concentrations of each metal and EPT richness were determined using quantile regression (the 90th quantile). Additionally, for this analysis, we used a function to identify a threshold concentration below which no effects were observed- taken to be the SC. The SCs (and 95% confidence intervals) of copper, zinc, cadmium, and manganese were estimated at 8.1 (1.9-20.8), 60 (26-405), 0.07 (0.01-0.45), and 3.9 (1.0-21.7) µg/L, respectively. We compared these values for copper, zinc, and cadmium with PNECs from EU risk-assessment reports and environmental water quality standards in the UK and US. Despite being derived from laboratory toxicity tests, most of these laboratory-based SCs overlapped with our estimates. To our knowledge, this is the first study to estimate the SCs from geographically widespread field data on macroinvertebrate surveys.

**Requirements for Terrestrial Model Ecosystems (TME) in Environmental Risk Assessment - influence of coring sites and management on microarthropod communities**

A Toschki[1], M Hammers-Wirtz[1], C Hoelscher[2], M Ross-Nickoll[2], B Theissen[3]
[1]Gaiac, AACHEN, Germany
[2]Institute for Environmental Research, AACHEN, Germany
[3]Bayer Crop Science AG, MONHEIM, Germany

Terrestrial Model Ecosystems (TME) can serve as an intermediate tool between laboratory and field tests in the Environmental Risk Assessment (ERA) of plant protection products and have been proven to be a suitable test system for a refined risk assessment. These outdoor test systems realistically represent the field situation and allow the examination of effects on complex soil communities at different trophic levels. At RWTH Aachen University in cooperation with Bayer CropScience a structural higher-tier TME-test system in soil ecotoxicology has been developed which is now considered to be ready for routine operations.

The initial situation of a TME study as well as the test conditions in the course of a one year study can be quite variable depending on the selected habitat for coring the test units and the management of the TME. Habitat selection and maintenance of the soil community are crucial issues, determining the representativeness, reproducibility and thus the validity of a test. Important aspects regarding the choice of the TME habitat are 1.which target community (off-crop/in-crop) we want to test, 2. are there minimum requirements concerning the diversity and community structure of the TME site and 3. which management strategies are suitable to sustain a stable test community over a one year period?

To answer these questions we tested the influence of different habitat management strategies on the soil microarthropod community (Collembola, Acari) in TME from two different coring sites. Additionally we tried to examine whether the management of the vegetation (mowing, fallow, mulching) within the test units (TME) has an influence on the population dynamics of the soil microarthropod community. The results indicate that our strategy of TME testing over the last years fulfils essential criteria of a semi-field test system within the ERA.

**Benthic microcosm; tool for toxicity estimation on ecosystem level**

GS Park[1], SJ Yoon[1], SM Yoon[2], KS Park[2], KS Kim[1], MJ Lee[1]
[1]Anyang university, INCHEON, South-Korea
[2]RIST, POHANG, South-Korea

Sixteen week outdoor benthic microcosm experiment was conducted to evaluate the effects of sewage sludge on benthic invertebrate colonization from May to September 2010 in intertidal mud flat. Re-colonization of macro/meiobenthos and chemical characterization were observed and analyzed using 2 factor ANOVA design (3X3X3); three sewage concentrations, three segment groups within microcosm, and three replicates for each treatment group. Changes of macro/meiobenthis, ignition loss (IL), COD, total sulfur (TS) and water contents (WC) were observed every three week period. Sewage concentration was major effect on changes of IL, COD, TS and WC with time, and the number segments within microcosm showed significant effects on changes of benthic community. This study was focused on the segmentation effects on recruitment of benthos within microcosm and revealed that segmentation can improve the colonization of benthic community in toxicity test at ecosystem level. Accordingly, segmented microcosm (small plastic basket) can be a useful tool for toxicity estimation at ecosystem level. This research was funded by Ministry of Land, Transport, and Maritime Affairs, Korea.

**Comparative sensitivity and recovery of structural and functional endpoints to fungicide chronic exposure in artificial streams**

Y Bayona[1], M Roucaute[2], K Cailleaud[3], A Basseres[3], L Lagadic[2], T Caquet[2]
[1]INRA UMR 985 \Total Petrochemicals PRDML, RENNES, France
[2]INRA, UMR985 Équipe Écotoxicologie et Qualité des Milieux Aquatiques, RENNES, France
[3]Total Petrochemicals, PRDML, LACQ, France

Ecological risk assessment of chemicals at the community level is usually based on the measurement of various parameters that derived from those used in ecological studies. Although these parameters are well suited to assess the acute/short term responses to toxicants, they may be sometimes less efficient in documenting indirect or long term responses, including recovery of the stressed systems. Furthermore, most of these parameters refer to the structure of the communities whereas there is a growing interest in the assessment of functional consequences of chemical stressors. A 5-month long experiment was performed into 40-m long outdoor flow-through experimental streams (volume : 6 $m^3$) to compare the responses of structural (taxonomic richness of invertebrate community and abundances of the various invertebrate groups, periphyton composition and biomass) and functional (alder litter breakdown, food web functioning) parameters to pesticide exposure. After a two-month stabilization period, 4 streams were treated with thiram, a dithiocarbamate fungicide (nominal concentrations: 35 and 170 µg $L^{-1}$; 2 replicates per concentration). Continuous exposure was carried out for three weeks and four untreated streams were kept as controls. Exposure was followed by a two-month long recovery period. In this presentation, the temporal dynamics of water physico-chemical characteristics (including thiram residues), periphyton composition and biomass, benthic invertebrate community structure and litter breakdown in control and treated experimental streams are presented. The sensitivity and the recovery dynamics of the various endpoints are compared and discussed.

**Ecotoxicology study of new butachlor CS formulation in Korean rice paddy field**

SH Im
Dongbu hannong Co., Ltd. / agrolife research institute, DAEJEON, South-Korea

Butachlor CS(capsule suspension) formulation was newly developed to decrease risk of oriental weatherfish which is the major biometer of Korean agricultural ecosystems. Ecotoxicology studies of acute, Semi-field and agricultural field study were performed using oriental weatherfish. Acute toxicity study was performed by test guidelines of Rural Development Administration, Korea. Semi-field study was experimented in rice paddy field which was divided to 3 plots(each plot 2.5 x 4.0 m). Each plot contains 5 cages with 20 oriental weatherfish. Mortality and abnormal behaviour were under the criteria of observation for 23 days after the application of butachlor CS formulation. During the experiment, paddy water and soil were sampled and analyzed. Agricultural field study was performed at the conventional rice cultivation conditions. The paddy field(1500m2) was divided to 3 plots(500m2), sprayed butachlor CS formulation and harrowed at the same time, and then planted rice. Each test plot contained 1000 oriental weatherfish which were 10 cages with 10 weatherfish, and 900 out of cages. Bird netting was set to protecting from the birds. Mortality and abnormal behaviour were under the criteria of observation for 21 days after the treatment of butachlor CS formulation. During the experiment, paddy water and soil were sampled and analyzed. According to results of the acute toxicity study, butachlor CS formulation's risk was lower than six times compared to already-in-use product. Cumulative mortality of butachlor CS formulation in semi-field study was resulted in significantly lowered to 5% compared to that of 64 ~ 97% of already-in-use product. In agricultural field study, the cumulative mortality of oriental weatherfish was 0% in the case of butachlor CS formulation. In cnclusion, new developed butachlor CS formulation was very low ecological risk to the oriental weatherfish.

**A multi-trial approach for estimating potential ecotoxicological effects of an industrialized area**

T Campani, I Caliani, N Bianchi, MC Fossi, C Leonzio
University of Siena, SIENA, Italy

The aim of this study was to evaluate, by means of biomarkers and the analysis of contaminants and trace metals, the toxicological impact caused by the emission from an hazardous waste incinerator plant using the Italian wall lizard (Podarcis sicula) and the leaves of downy oak (Quercus pubescens) as biomonitor species. The study area is one of the most important gold and silver manufacturing area in Europe and is also characterized by the presence of an hazardous waste incinerator and two of the major national roads: the A1 highway and the high speed railway line. The lizard for its physiological and ecological characteristics is a powerful bioindicator; it has a limited home range and it is widely distributed in the urban environment. The downy oak has a wide distribution into the study area and is characterized by the presence of leaf with hairy surface that entrap the particulate matter. In order to obtain a more representative sampling design of the flow of incinerator emission into the atmosphere it has been applied a theoretic diffusion model which it has been validated through the detection of the cadmium concentration as a tracer metal accumulated into the leaves of downy. After this phase, the downy oak was used as a vegetal bioindicator to evaluate the presence of trace elements accumulated on the leaf surfaces by the atmospheric deposition. In a second phase, a set of biomarkers (EROD activity, uro- copro and proto-porphyrins, Comet assay and ENA assay) and the levels of contaminants (PCB and Dioxins) and trace metals (Cd, Hg, Pb, Zn) were evaluated in 47 specimens of the Italian wall lizard collected in sampling station that has been selected according to the diffusion model data. The results showed a good relationship between the theoretical model and the concentration of trace metal into the leaves. The results of the biomarkers and the analysis of contaminants evaluated in the Italian wall lizard, showed an high sensitivity of the bioindicator species. In conclusion the results obtained underline how the use of a multi-trial approach based on biomarker responses and contaminant levels in bioindicator species is a simple and effective method for the evaluation of possible impacts caused by a contamination from any type of industrial plant.

**MO 335**

**Ecological diagnosis of pollution impacts by weight of evidence**

SE Marshall[1], BS Gagliardi[1], A Kumar[2], VJ Pettigrove[1]
[1]CAPIM, The University of Melbourne, PARKVILLE, Australia
[2]CSIRO Land and Water, GLEN OSMOND, SA, 5064, Australia

A recent survey of sediment quality in Melbourne and the Yarra Valley found elevated concentrations of a range of pesticides (1). Because contaminants typically occur in combination, and guideline concentrations exist for few of the detected pesticides, predicting the ecological impact of contaminated sediment is a complex issue. We applied a weight of evidence approach to three complementary sediment toxicity bioassays to diagnose both the severity and type of ecological impact. We measured community compositional change in a field microcosm bioassay, deformity rates in wild Chironomus spp, and growth, emergence and survival in laboratory-reared C. tepperi. The field microcosm bioassay provided an ecologically relevant benchmark by estimating the impact of sediment pollution on invertebrate community composition. Pesticides and heavy metals were linked with two distinct types of microcosm community change. In wild Chironomus spp, heavy metals were specifically associated with mentum deformities, while pesticides were associated with deformities of the pectin epipharanges. Sites where impacts were identified by both laboratory C. tepperi bioassay and wild Chironomus spp deformity rates tended to also display community impacts in the field microcosm bioassay. We conclude the C. tepperi test was the most sensitive of the three bioassays, deformities suggested more severe toxicity, and microcosm community change indicated the most severe toxicity. The combined bioassays provide useful evidence regarding the type of contamination responsible for the observed toxicity.

**Characterizing off-field vegetation for NTA terrestrial mesocosm studies**

S Aldershof
Bioresearch & Promotion, AMSTERDAM, The Netherlands

In contrast to in-crop environments, the habitat for studies with non target arthropods in natural off-field environments can as a matter of fact not be standardized. Because the composition of the arthropod fauna is closely linked to the local flora there is a clear need to characterize the vegetation of such a study site. This is not only needed to assess the within study variation in habitat characteristics as a basis for blocking, but also to enable a future classification/comparison of off-field studies. Here we present a simplified standard method to assess plant diversity and relative abundance of grassland vegetations. The method involves releves of units consisting of eight small squares, using presence/absence sampling, performed on regular grid imposed over the study site. The data analysis uses Twin Span and correspondence analysis to quantify similarities in vegetation structure within the study site.

[4]University of Exeter, PENRYN, United Kingdom
[5]The Agri-Food and Biosciences Institute, OMAGH, United Kingdom
[6]Science and Advice for Scottish Agriculture, EDINBURGH, United Kingdom

The small mammal prey guild in Ireland is restricted compared with that in Britain but still includes species most likely to consume anticoagulant rodenticides (AR) baits, the biocides that are the most widely used globally to control rodents. We hypothesise this restricted prey guild will enhance secondary exposure of predators and the associated risk of secondary poisoning. We determined, from the presence of liver residues, the exposure of 115 foxes (Vulpes vulpes) to ARs (predominantly second-generation anticoagulant rodenticides) that were shot or killed by traffic in Northern Ireland (NI). Exposure to the more toxic ARs, flocoumafen and brodifacoum, was more prevalent than in foxes from elsewhere in the UK and reflect greater use of these compounds by farmers in NI. Exposure to ARs generally was greater (% of animals exposed and/or magnitude of residues) in lowland than upland animals, probably due to greater availability and consumption of AR-contaminated small mammals in lowland habitats. Overall, 84% of the foxes tested had detectable liver residues and exposure was greater or similar to that in samples of foxes from Scotland and from England and Wales, despite the British samples being biased towards suspected poisoned animals. High exposure in NI foxes is most likely explained by greater predation of commensal rodents and those non-target species most likely to take AR baits. Our data are consistent with the hypothesis that the reliance of small mammal predators in Ireland on a restricted prey guild enhances their exposure to ARs. We argue that Ireland may be a sentinel for the UK in terms of likelihood of AR-mediated effects on predator populations.

**MO 340**

**Estimation of emission from treated wood: evaluation of experience under the EU Review Program of the Biocidal Products Directive**

VIR Unamuno[1], L van der Wal[1], E van de Plassche[2]
[1]Institute for Health and Consumer Protection, Joint Research Centre, ISPRA, Italy
[2]European Chemical Agency (ECHA), Unit A.2-Committees and International Relations, HELSINKI, Finland

Chemicals such as biocides contained in Wood Preservatives, can leach from the wood to the environment being a cause of environmental and health concern. Once in the environment, the biocide residue can be immobilised and degraded in soil, or transferred to the other compartments in the environment.

In 1998, Directive 98/8/EC of the European Parliament and of the Council on the placing on the market of biocidal products was adopted. The Directive aims to provide a high level of protection for humans, animals and the environment. Wood Preservatives are defined as Product Type 8 and are among the priority substances to be assessed.

For Annex I inclusion, an environmental assessment is required. For Wood Preservatives, this methodology requires the determination of: leaching rates from treated wood, exposure rates, and environmental effects. The main issue of the Review Program for biocidal substances (2000-2004) was that none of the existing draft guidelines were validated and the lack of international harmonisation. The Leaching Workshop organised in 2005, aimed to solve this issue.

The majority of the substances used in Wood Preservatives have now been assessed in the Review Program. In addition product authorization has also started. As a consequence, there is a need to re-evaluate the results on the Leaching Workshop in the light of the experience gained so far in the Review Program. In addition, ongoing recent developments within the OECD and CEN have to be considered

**MO 341**

**Harmonising the exposure assessments for rodenticides: finalising the revision of the Emission Scenario Document for PT14.**

L van der Wal[1], E van de Plassche[2]
[1]European Commission/Joint Research Centre, ISPRA (VA), Italy
[2]European Chemicals Agency (ECHA), HELSINKI, Finland

The Technical Guidance Document (TGD) published by the European Commission provides guidance for the overall risk assessment of chemical substances including active substances for biocidal products. Specific guidance on the exposure assessment of these active substances has been provided for in Emission Scenario Documents (ESDs), which were developed per biocidal product type in the EUBEES 2-project.

The first active substances for biocidal products of the first priority list (product types 8 and 14) have been included in Annex I or IA of the Biocidal Product Directive 98/8/EC and experience has been gained with the use of ESDs.

More specifically, during the evaluation of active substances for product type 14 (rodenticides), the need for a revision of the guidance related to the assessment of primary and secondary poisoning became clear and subsequently an update and harmonisation of this assessment was endorsed at the 23rd Meeting of Competent Authorities.

Currently, the revision of the ESD for product type 14 is ongoing, which will include an updated section on the issue of primary and secondary poisoning of non-target animals exposed to rodenticides as well as a harmonisation with other risk assessment schemes (i.e. EFSA). Additionally, the issue of exposure of target- versus non-target animals and possible risk management measures will be addressed.

**MO 342**

**Risk assessment of fungicides and bactericides: are we using the correct data?**

N Chevre[1], DR Johnson[2], JR van der Meer[1]
[1]Université de Lausanne, LAUSANNE, Switzerland
[2]ETHZ, ZÜRICH, Switzerland

Risk assessment is conventionally performed by comparing measured or predicted environmental concentrations with a concentration that should protect the ecosystem on a long-term perspective. This protective concentration is calculated based on a set of ecotoxicological data and we assume that the diversity of the data from this set represents the diversity of species we can find in the ecosystem. In reality, ecotoxicological data are collected in databases and the species represented are mostly limited to daphnids, some algae and some fish, that do not represent the richness of the ecosystem. This is particularly problematic when trying to evaluate the risk of specific acting compounds like fungicides and bacteriocides that have a mechanism of action developed to affect fungi or bacteria. Indeed, neither fungi nor bacteria are well represented in ecotoxicology databases. In this study, we tested two fungicides, metalaxyl and propiconazol, and one bacteriocide, triclosan, on different bacteria and yeasts. The results were compared with species sensitivity distribution curves constructed with conventional ecotoxicological data obtained from databases. In general, the yeasts and bacteria were not more sensitive than the other species. However, for both metalaxyl and triclosan, yeast and bacteria were among the most sensitive species.

Furthermore, we also tested one substance, triclosan, on a natural microbial community, which was shown to be more sensitive than any single species. Indeed, 3 ug/l was sufficient to change the phylogenetic composition of the community. It seems therefore crucial to include effect data obtained with yeasts, bacteria, fungi and even whole microbial communities when calculating protective concentrations for fungicides and bacteriocides.

**MO 343**

**Are HC5 values derived from toxicity tests with fish, invertebrates and primary producers protective of aquatic fungi?**

S Kosol[1], RPAv Wijngaarden[2], MR Dimitrov[3], TCM Brock[2], L Maltby[1]
[1]The University of Sheffield, SHEFFIELD, United Kingdom
[2]Alterra, Wageningen University and Research Centre, WAGENINGEN, The Netherlands
[3]Laboratory of Microbiology, Wageningen University, WAGENINGEN, The Netherlands

Aquatic ecological risk assessment for fungicides in Europe does not currently assess risk to fungi. Rather, regulatory acceptable concentrations based on ecotoxicological data for fish, invertebrates and primary producers are assumed to be protective of all other aquatic organisms. Here we explore the validity of this assumption by investigating the effects of a fungicide applied at the HC5 concentration (derived from single species toxicity tests on fish, invertebrates and primary producers) on the abundance and functioning of aquatic hyphomycetes in semi-field studies. The study was performed in enclosures placed in an experimental ditch system at Sinderhoeve experimental station, The Netherlands. A single application of tebuconazole (238 µg/l) was applied to four enclosures and another four enclosures were used as controls. The experiment ran for 52 d and aquatic hyphomycete abundance and leaf decomposition rates in enclosures receiving tebuconazole were compared to those of control enclosures. In addition, the consumption by invertebrates (*Gammarus pulex*) of leaf material from treatment and control enclosures was compared in an additional laboratory experiment. Tebuconazole exposure caused some change in the abundance (as conidial production) of the dominant aquatic hyphomycetes species (*Anguillospora longissima* and *Tetracladium setigerum*), but had no effect on leaf decomposition rates. There was, however, a significant reduction in the consumption rate of Gammarus pulex when fed tebuconazole-exposed leaf material.

**MO 344**

**Fungal community structure and functioning in arable and non-arable streams**

S Kosol, L Maltby
The University of Sheffield, SHEFFIELD, United Kingdom

Microbes, in particular fungi, play an important role in the ecology of streams by making energy and nutrients locked away in dead organic matter available to aquatic organisms. Agricultural practices may impact stream communities by altering habitats or by reducing water quality through increased nutrient and pesticide concentrations. The risks of pesticide exposure to aquatic animals and plants are well studied, but little is known about the risk posed to fungi; despite many pesticides being fungicides. Here we investigate the impact of arable farming, including pesticide application, on the structure and functioning of aquatic hyphomycetes, a key group of stream fungi. Fungal community structure, biomass, leaf decomposition rates and utilization of leaf litter by shredding invertebrates (i.e. *Gammarus pulex*) was assessed for 5 pairs of arable and non-arable streams in Lincolnshire, United Kingdom. Arable streams supported lower fungal diversity, lower fungal biomass and lower leaf decomposition rates than non-arable streams. However, the consumption of leaf material by shredders was increased when leaf material was conditioned in arable streams.

**MO 345**

**The effects of three pesticides on the growth of Euglypha rotunda (Rhizaria; Euglyphida): is this species a good bioindicator?**

T Perruchoud[1], N Chèvre[1], M Edward[2]
[1]Université de Lausanne, LAUSANNE, Switzerland
[2]Université de Neuchâtel, NEUCHÂTEL, Switzerland

In this study we investigated the effects of pesticides on a common soil testate amoeba species (*Euglypha rotunda*). *E. rotunda* and other free-living euglyphid soil protozoa play important ecological roles in the soil microbial loop as bacterial predator and in the cycling of silica. However, effects of pesticides have never been tested on these organisms. Imbalanced selection of model organisms in ecotoxicology could potentially cause erroneous assessment of true environmental impact of pesticides and pollutants on soil biodiversity and ecosystem function. We therefore evaluated the effect of three pesticides, the herbicide glyphosate (Roundup active ingredient), the fungicide carbendazim (Carbendazim SA 60 FL active ingredient) and the insecticide thiacloprid (Alanto active ingredient) on the growth of *E. rotunda*. We assessed population growth of *E. rotunda* after exposure at following concentrations ranges: 0.1 - 10 mg/L glyphosate, 0.1 - 2 mg/L carbendazim and 10 - 1000 ng/L thiacloprid cultured in NCL 0.1% media during 21 days of incubation. The results showed that both the fungicide and the insecticide decreased the growth of *E. rotunda*, even at low concentrations. Thiacloprid inhibited totally the growth of *E. rotunda* in all the range of concentration tested. Carbendazim caused a total growth-inhibition at a concentration of 1 mg/L and a partial growth-inhibition at a concentration of 0.1 mg/L. By contrast, glyphosate stimulated the growth of *E. rotunda* at concentration of 10 mg/L but no effect was detected at 1 mg/L. These results show than *E. rotunda* reacts differently when exposed to different pesticides and is highly sensitive to some such as thiacloprid. We therefore suggest that it could be a good bioindicator to be tested to evaluate the effects of pesticides.

**MO 346**

**Does the length of the interval between repeated pulses influence the effect of the pesticide permethrin on Hyalella azteca?**

S Pedersen[1], V Forbes[2], A Palmqvist[2]
[1]Roskilde University, ROSKILDE, Denmark
[2]Department of Environmental, Social and Spatial Change, ROSKILDE, Denmark

Exposure of non-target aquatic organisms to pesticides is likely to occur in short pulses following periods of drain flow, surface run-off or spray drift. Since standard aquatic toxicity tests for acute effects assessment are primarily based on continuous and maintained exposure periods of 24 to 96 hours, there is a mismatch between laboratory and field exposure patterns. This has potential implications for standard risk assessments and could result in over- or underestimation of risk. The aim of the present study was to examine the effect of different time intervals between two pulses of the pyrethroid insecticide, permethrin, on the freshwater amphipod Hyalella azteca. Permethrin is used in mosquito control and to control a wide range of insect pests on various crops and is known to be highly toxic to aquatic invertebrates. H. azteca is widely distributed throughout North America and is a common food source for birds, fish and large invertebrates. It is therefore considered to be an ecologically important species. In addition, H. azteca has been extensively used as a test organism and is generally sensitive to contaminants.
H. azteca were exposed to two repeated pulses of one hour each with different intervals between the two pulses. The nominal exposure concentrations were 0, 0.3 or 0.9 µg/L, and the intervals between the pulses were 0, 6, 24, 48 or 144 hours. After each pulse the organisms were transferred to clean water. Survival was recorded immediately after the pulses and again after 10 days from the start of the experiment.
The implications of having different intervals between pulses will be discussed.

**MO 347**

**Invasive freshwater crayfish: a new ecosystem component and its challenge to risk assessment**

I Roessink[1], N Galic[2], S Hudina[3]
[1]Alterra, Wageningen UR, WAGENINGEN, The Netherlands
[2]Wageningen University, WAGENINGEN, The Netherlands
[3]University of Zagreb, ZAGREB, Croatia

Due to their high commercial value exotic freshwater crayfish have been introduced to many freshwater ecosystems. Being very mobile and able to escape designated water bodies over land crayfish soon spread far beyond their initial points of introduction. Today almost every European country harbors at least one species of exotic crayfish.
Being carriers of the fungal infection known as crayfish plague (lethal to indigenous crayfish) and strong ecosystem engineers through mechanical interference or active predation freshwater crayfish heavily impact macrophytes, invertebrate and vertebrate communities in many ways and therefore are often considered pests. However, invasive crayfish have also become an important part of the diet of larger fish, birds, and mammals. In combination with strong crayfish feeding on organic matter this might result in an additional exposure route in the food chain.
Although being hardy creatures, its large size and aggressive territorial behavior make most crayfish challenging test subjects in the laboratory. In this poster we present several tried techniques used in crayfish testing and provide solutions covering the challenges crayfish pose to risk assessment.

**MO 348**

**Population-level effects of spinosad and Bacillus thuringiensis israelensis in Daphnia magna: comparison of laboratory and field microcosm exposure conditions**

C Duchet[1], MAC Coutellec[2], EF Franquet[3], CL Lagneau[1], LL Lagadic[2]
[1]EID Méditerranée, MONTPELLIER CEDEX 4, France
[2]INRA, RENNES, France
[3]IMEP, MARSEILLE, France

Because exposure to toxicants not only results in mortality but also in multiple sublethal effects, the use of life-table data appears particularly suitable to assess global effects on exposed populations. The present study uses a life table response approach to assess population-level effects of two insecticides used against mosquito larvae, spinosad (8 µg/l) and *Bacillus thuringiensis var. israelensis* (*Bti*, 0.5 µl/l), on *Daphnia magna* (Crustacea: Cladocera), under laboratory versus field microcosms conditions. Population growth rates were inferred from life table data and Leslie matrices under a model with resource limitation (ceiling). These were further used to estimate population risks of extinction under each tested condition, using stochastic simulations. In laboratory conditions, analyses performed confirmed the significant negative effect of spinosad on survival, mean time at death, and fecundity as compared to controls and *Bti*-treated groups, population growth rate $\lambda$ was lower under exposure to spinosad. In field microcosms, 2 days after larvicide application, population growth rate was significantly lower under spinosad exposure conditions than under control and *Bti* exposure conditions. Simulations performed on spinosad-exposed organisms led to population extinction (minimum abundance = 0, extinction risk = 1), and this was extremely rapid (time to quasi-extinction = 4.1 one-week long steps, i.e. one month).

**MO 349**

**Status of guidance documents for environmental risk assessment of plant protection products at EFSA**

M Egsmose, S Bopp, K Nienstedt, S Suciu
European Food Safety Authority, PARMA, Italy

Since 2006, EFSA's PPR Panel has been responsible for the update and development of EU Guidance Documents (GDs) for Environmental Risk Assessment (ERA) of Plant Protection Products. Since October 2008, the EFSA Pesticide Steering Committee (consisting of Member States, the Commission and EFSA representatives) has been responsible for setting priorities for needs of new Guidance or updating existing GDs for risk assessment of Plant Protection Products (PPPs). An update on the ongoing work, as well as an outlook of ongoing activities in the PPR Panel, will be given:
Revision of the GD on Persistence in Soil, New GD on Emission from Protected crop system (Green-houses and Covered crops), Revision of the GD on Aquatic Ecotoxicology and the Revision of the GD on Terrestrial Ecotoxicology.
Besides the update and expected time-lines for the ongoing activities, an outlook for upcoming requests for revision or new GDs and Opinions will be presented.

**MO 350**

**Database compilation on pesticide ecotoxicological tier 1 study endpoints using IUCLID 5.2 as data entry software**

KM Nienstedt[1], J Richardson[1], V Croce[2], S Barmaz[2], S Maroncelli[2], C Neri[2], SK Bopp[1]
[1]EFSA European Food Safety Authority, PARMA, Italy
[2]ChemService S.r.l., NOVATE MILANESE (MI), Italy

In 2009, EFSA's PPR unit has received two mandates for revising the current Guidance Documents (GDs) on Aquatic Ecotoxicology (SANCO/3268/2001) and Terrestrial Ecotoxicology (SANCO/10329/2002) regarding the placing of plant protection products (PPPs) on the market. In this context, the validation of Toxicity Exposure Ratios (TERs) used in these GDs is needed. As a requisite for this, it was decided to create a database on ecotoxicological properties assessed at Tier 1 level for all available active substances and PPPs dossiers submitted under Directive 91/414/EEC, that contain also higher tier ecotoxicology studies. The data entry has been outsourced in 2009 according to EFSA procurement procedures and fully carried out at EFSA premises by ChemService.
The database contains all available tier 1 study endpoints for aquatic organisms, bees, non target arthropods, non target plants and soil organisms, for the dossiers where higher tier ecotoxicology data for any of these taxa are available. This amounts to 227 dossiers corresponding to 104 active ingredients and 123 PPPs. The data has been collated using IUCLID 5.2 software which has a data structure based on the OECD harmonised template for reporting chemical test summaries. This option was selected since the harmonised template is an international data standard which is

used for instance by ECHA for the REACH process and for the submission of biocidal products dossiers according to the EC Directive 98/8. The IUCLID interface ensures that entered data is in a format suitable for querying and statistical analysis, the query plug-in tool assists in data quality checks and the IUCLID system supports the export of data in XML format to facilitate data sharing.
The database will be further populated entering tier 1 study endpoints for all available dossiers, i.e. also those not containing related higher tier studies, following a mandate received by the European Commission (EC) in 2010, to compile such a database covering all available ecotoxicology tier 1 data. These data are intended to be used by the EC and the European Member States in the context of the new legislation Regulation (EC) 1107/2009 concerning the placing of plant protection products on the market, Regulation (EC) No 1185/2009 concerning statistics on pesticides, and Directive 2009/128/EC establishing a framework for Community action to achieve the sustainable use of pesticides.

**MO 351**

**Risk mitigation measures in the framework of the council Directive 91/414 EU**

JH Herranz, DA Auteri, FS Streissl
EFSA, PARMA, Italy

According to Directive 91/414/EEC pesticides are listed in Annex I ("positive list") if at least one representative use does not pose "unacceptable"effects to humans and to the environment on the basis of a risk assessment process. EFSA (the Pesticide Risk Assessment Peer Review Unit - PRAPeR) is responsible for the peer review of risk assessments of active substances in Europe. The EFSA conclusion lists reference values and endpoints, identifies particular conditions that may need to be considered in relation to the risk, and the critical areas of concern. In the particular conditions of the conclusion, risk mitigation measures proposed in the ecotoxicology section are included.
If a potential high risk would be identified at the higher tier risk assessment for non-target species then risk mitigation measures were necessary to reduce the adverse effects of the active substance for the non-target species.
Different risk mitigation measures are contemplated for birds and mammals, aquatic organisms, bees, non-target arthropods and non-target plants (guidance documents on risk assessment for birds and mammals, SANCO 4145/2000, aquatic ecotoxicology, SANCO 3268/2001 and terrestrial ecotoxicology SANCO 10329/2002) at EU level. .
Guidance document "landscape and mitigation factors in aquatic ecological risk assessment"is currently available to harmonise the mitigation measures for aquatic organisms. However, there are currently no guidance documents to harmonise the mitigation measures required for birds and mammals, bees, non-target arthropods and non-target terrestrial plants.
The aim of this work is to give an overview of the mitigation measurements presented for the active substances suggested in the EFSA conclusion for non-target species. Critical issues and the need of further improvement will be discussed.

**MO 352**

**Hellenic scenarios for bird focal species: the case of the cotton fields**

M Foudoulakis[1], D Tzakos[1], N Kostouros[1], E Kaniastas[2]
[1]Agricultural University of Athens, ATHENS, Greece
[2]Hellenic Ornithological Society, ATHENS, Greece

In Europe, the risk to birds from plant protection products (PPP) needs to be evaluated under the provision of Council Directive 91/414/EEC and associated documents. In many cases, a refined risk assessment is necessary, for which the identification of actual bird species more likely to be exposed to a PPP is often a pre-requisite. While several studies have been conducted in typical crops of central temperate Europe, less information is available for crops specific to Mediterranean countries, like cotton.
In this study, we present information about bird species observed in cotton fields in two regions of Hellas (Kopaida and Larisa) in two field seasons in spring and summer using two bird survey methods ('line transects' and 'point counts').
The most frequent and abundant species found in cotton fields in the two regions were the house sparrow and the barn swallow. The crested lark was often observed in Larisa but much less frequent in Kopaida. Other candidates for focal species were yellow wagtail, european bee-eater and greater short-toed lark. Among the larger species, common kestrel and lesser kestrel (Falconidae), carrion crow, european magpie and eurasian collared dove were identified as the most common species. The selection of bird focal species for the refined risk assessment of plant protection products used in cotton is further discussed.

**MO 353**

**Foraging habitat of hedgerow bird species in arable land and its relevance to in-crop exposure to plant protection products**

M Foudoulakis, N Kostouros, D Tzakos
Agricultural University of Athens, ATHENS, Greece

In Europe, the risk to birds from plant protection products (PPP) needs to be evaluated under the provision of Council Directive 91/414/EEC and associated documents. In many cases, a refined risk assessment is necessary, for which the identification of actual bird species more likely to be exposed to a PPP is often a pre-requisite. While several farmland species are clearly exposed as they use primarily the in-crop field as foraging habitat, there is little information about potential exposure of those hedgerows species living in field margins adjacent to arable fields.
In this study, we provide information regarding the relevance of the in crop area as a habitat use for the hedgerow bird species in lowland-farming landscapes in order to provide a background against which decisions concerning risk assessment from the pesticide applications might be evaluated. The study was conducted in spring and summer in during 2009 in two predominantly agricultural areas of Hellas (Kopaida and Larisa) that differed in the relative frequency and complexity of hedgerows between the arable fields. Main crops were cotton, cereals and alfalfa. Birds were observed using the 'point count' method conducting a high number of observation sessions (459 sessions), each lasting 10 minutes (total observation time=4590 minutes). The number of species and individuals and time (minutes) spent by each individual in all habitats (mainly cotton but also in alfalfa and cereals) was recorded.
In Kopaida (160 sessions), a total of 35 species (of which 12 hedgerow species) was observed. In Larissa (299 sessions) the total number of species was 33 (9 hedgerow species). In both study areas, irrespective of the type and size of hedgerows, only a minor proportion (2 out 21) hedgerow species visited and potentially fed in the crop. The two hedgerow species visiting the crop (Remiz pendulinus and Acrocephalus schoenobaenus) spent a small proportion of the total observed time. Despite the different agricultural landscapes in Kopaida and Larisa, the behaviour of the hedgerow bird species was similar: feeding events within the crop appear to involve a minor proportion of the foraging time of hedgerow species. The extrapolation of these results to other regions and their implication for the regulatory risk assessment of PPPs in Europe is further discussed.

**MO 354**

**Probabilistic ecological risk assessment of eleven paddy herbicides**

T Nagai
National Institute for Agro-Environmental Sciences, TSUKUBA, Japan

Probabilistic ecological risk assessment of 11 herbicides, commonly used in Japanese paddy fields was conducted. The effect assessment was based on species sensitivity distribution (SSD). The acute EC50 values of standard toxicity tests for aquatic primary producers were collected from available literatures and then fitted into lognormal distributions. Predicted environmental concentration (PEC) was calculated using an environmental model defined by the Ministry of Environment, Japan. The regional variations of PEC were quantified using Monte Carlo analysis. A joint probability curve was derived by comparing SSD and PEC distribution, and the area under the curve was defined as expected potentially affected fraction (EPAF) for quantitative risk index. The highest EPAF was 6.2% for bensulfuron-methyl.

**MO 355**

**Higher-tier surface water risk assessment according to ELINK**

R Sur, B Koch, C Kley, E Bruns
Bayer CropScience AG, MONHEIM AM RHEIN, Germany

For a herbicide a higher-tier aquatic risk assessment was performed. One pillar was a mesocosm study. A lower-tier exposure calculation only provides a single worst-case drainage/run-off entry peak and does not take into account the duration of the exposure. It was challenged by authorities whether the exposure pattern in the mesocosm study covers the real environmental exposure situation for run-off and drainage entries with respect to peak height, duration, and area under the curve. Based on the recommendations of the ELINK workshop and using representative FOCUS surface water scenarios the suitability of the mesocosm study was demonstrated. For that purpose the "envelope curve concept"was applied comparing exposure concentrations observed in the mesocosm and time-resolved PECsw originating from FOCUS Surface Water Step 3 calculations. By this procedure it was shown that the exposure pattern used in the mesocosm study covers the run-off and drainage exposure pattern at any time with a safety factor of at least 2.

**MO 356**

**New strategies in the risk assessment of plant protection products in soils**

S Pieper[1], B Scholz-Starke[2], JP Sousa[3], S Jänsch[4], J Römbke[4]
[1]German Federal Environment Agency, DESSAU, Germany
[2]Umweltbundesamt, DESSAU-ROβLAU, Germany
[3]Dept. Zoology, COIMBRA, Portugal
[4]ECT, FLÖRSHEIM, Germany

The risk for soil organisms arising from the exposure to plant protection products (PPP) is assessed by relating the effect concentration to the calculated predicted environmental concentration in the soil matrix (PECsoil). Currently, the PECsoil calculations are based on simple assumptions, e.g. on an homogeneous distribution of the substance in the first 5 cm of the soil profile. But, since neither the chemical properties of the applied substances nor the habitat preferences of the soil organisms are taken into account, the appropriateness of this approach in the risk assessment (RA) of PPP has been questioned. The German Federal Environment Agency (UBA) is currently working on the improvement of the risk assessment procedure for soil organisms as part of the national authorisation process of PPP. In this context, a re-evaluation of literature data and of earthworm field studies has been undertaken, with the aim of corroborating the key hypotheses on which the newly developed strategy is based and to assess the implications that will arise from the implementation of the new procedure for the outcome of the risk assessment of plant protection products in soil.The methodology chosen followed these step:s
- Functional characterization of life form types of Central European soil invertebrates (e.g. oligochaetes, microarthropods) at crop sites regarding their exposure to PPPs -with particular regard to different exposure pathways.
- Identification of "focal communities" of soil organisms regarding the exposure to PPP for combinations of crop types and tillage operations as indicators for the soil biocenosis.
- Analysis of the results of earthworm field studies with PPPs which were performed in the context of the registration of PPPs, in particular regarding of the representativity of the respective community on the control plots, the physico-chemical properties of the test substances as well as the sensitivity of the individual life form types.
- Indication of parameters for the derivation of the ecological relevant exposure concentrations of PPPs for soil organisms based on their life form types and exposure scenarios
- Discussion of possible effects of modified exposure calculations on the interpretation of the results of ecotoxicological standard tests with soil invertebrates, including the question whether existing test designs are still appropriate or should in future be modified.

**Plant protection products authorization in Poland. Actual and future requirements.**

M Bielasik-Rosinska, D Maciaszek
Institute of Environmental Protection National Research Institute, WARSAW, Poland

The submitted dossiers for plant protection products should contain study reports and calculation data for active substances and their metabolites according to requirements.
Physical and chemical properties of releasers and metabolites of their hydrolysis are essential for the risk assessment.
Assessment of predicted environmental concentration (PEC) for soil (PECS), ground water (PECGW) and surface water including sediments (PECSW and PECSED) should be based on proposed use of plant protection product (GAP) and European guidelines - FOCUS Working Group Guidance Documents. According for actual requirements, for Poland there are particular requirements for ground and surface water. The calculation for PECSW and PECSED are realized for STEP 1-2, STEP 3 and STEP 4.
For the ground water - all European scenarios are required, for the surface water - D3, D4 and R1 scenarios are obligatory. For some crops there is no scenarios for D3 or D4 or R1. In that case the worst scenarios is used as representative for Poland.
In future - Poland will be treated as Central Region State and according to such requirements all information should be submitted.
If metabolites properties confirm potential hazard for environment, then additional calculations for them are necessary and required. Evaluation of submitted reports and data for each active substance and its metabolites are considered for risk assessment. The final risk assessment and conclusion should include all available study results and information and should be compared with proposed GAP.

**MO 358**

**Lack of an understanding in correlating various legislations in an effort to harmonize a strategic solution to environmental risk assessment and management - The Indian experience**

V Saini
M/s. Pesticide Regulatory Affairs - INDIA, FARIDABAD ( HARYANA ), India

The Insecticides Act, 1968 and Rules, 1971 is the major legislation which deals with the regulation of PPP's and biocides. However, there are other legislations which are remotely associated with this Act., but with a poor understanding of their implications in making regulation harmonized amongst all enacted legislations in an effort to have a more effective risk management strategy. At present there is a poor understanding of any kind of risk management strategy in the country. The proposed Pesticide Management Bill 2008 too fails to address such concerns, which is still pending approval from the Lok Sabha ( Parliament of India ). The paper attempts to highlight the lack of a national commitment towards a harmonized approach to evaluating risk management in the country.

**MO 359**

**Hot-spot identification & management for surface waters in context of the German National Action Plan for Sustainable Use of Pesticides: the methodological framework**

B Golla, J Strassemeyer, V Gutsche
Julius Kühn Institute (JKI), Federal Research Centre for Cultivated Plants, KLEINMACHNOW, Germany

New EU legislation on the sustainable use of pesticides requires member states to produce 'national action plans' (NAP) on pesticides. The German NAP is designed to provide incentives for further risk reduction with the overall goal to reduce the risk potential by 25 % until the year 2020 in relation to the risk potentials calculated for a reference period from 1996 to 2005. A core component of the NAP is the management of hot-spots. They are defined as temporally and spatially defined fields of action with increased risk associated with plant protection products. Hot spots can occur due to specific environmental conditions (e.g. high water body density, high soil porosity), due to wide-spread and frequent use of a few plant protection products or due to high-frequency, crop and pests-related use of a specific plant protection product over a single area in connection with other conditions, such as frequent rainfall. Hot Spot detection & management follows a stepwise approach: The target of step one is a ranking of regions according to their aquatic risk potential using the indicator model SYNOPS-GIS and a subsequent in depth analysis at stream segment level for TOP regions. These in depth analysis apply probabilistic and spatial methods for more realistic exposure analysis linking critical source areas to receiving stream segments. The method requires recent regional pesticide use data, large scale soil data (1 : 50 000), weather data and explicit crop locations from the land parcel identification system (LISP) (EC No 796/2004). Results are aggregated to watershed units recognized also by the water framework directive (WFD). This common regional backdrop assures the link between activities of the WFD with the NAP. Monitoring data collected within WFD activities are used in the second step for validation purposes. In the third step existing regional risk mitigation measures (RMM) are reviewed and new management strategies are defined in cooperation with the official local extension services. These activities aims at providing regional "tool boxes"of RMM in order to strengthen the voluntary cooperation of farmers in water protection at local level. As the final step a model based control of success is performed to assess the regional effectiveness of the selected RMM before putting those into practice. This step is a partial run through step 1. First results of the implementation of this methodological framework are collected in North Rhine-Westphalia.

**MO 360**

**Hot-Spot identification & management for surface waters in context of the German national action plan for sustainable use of pesticides: first results**

J Strassemeyer, B Golla, J Krumpe, V Gutsche
Julius Kühn-Institut, KLEINMACHNOW, Germany

Within the National Action Plan the indicator model SYNOPS is applied for the analysis and detection of spatially defined regions with increased risk (hot spots) associated with plant protection products. These can occur due to specific environmental conditions (e.g. high water body density, high soil porosity steep slope), due to wide-spread and frequent use of a few plant protection products or due to high-frequency, crop and pests-related use of a specific plant protection product in connection with climate conditions, such as frequent rainfall.
In this study the provisional detection of such hot spots was conducted with SYNOPS-GIS in North Rhine-Westphalia on the basis of surveys on pesticide use and weather data from 2009 and extended GIS datasets such as the "Land Parcel Identification System (LPIS)". Three watersheds with high aquatic risk potential were identified. Here an in depth risk analysis was conducted at the level of stream segments.
The time varying concentration of the selected stream segments was analysed over the whole vegetation period considering the exposure pathways drift and run-off. A GIS evaluation on the entrance points and runoff-pathways from critical source areas was conducted. In combination with a run-off model the initial load of the stream segments by run-off was evaluated. Drift loads were assessed with a probabilistic approach. Stream segments which exceed a certain trigger concentration were identified and segments with specific concentration pattern in given time windows could be addressed. With this approach different scenarios of risk mitigation measures were analysed and compared, like the compliance to product specific drift mitigation requirements and the implementation of fixed non crop zones.

**Derivation of environmental quality standards for plant protection products: factors influencing the outcome**

M Junghans[1], C Perazzolo[2], N Chèvre[2], C di Paolo[1], M Duchemin[3], RIL Eggen[4], R Gälli[5], V Gregorio[2], A Häner[5], N Homazava[1], R Kase[1]
[1]Swiss Centre for Applied Ecotoxicology Eawag-EPFL, DUEBENDORF, Switzerland
[2]University of Lausanne, LAUSANNE, Switzerland
[3]CEHTRA (Lyon Agency), VAULX MILIEU, France
[4]Eawag, DUEBENDORF, Switzerland
[5]BMG Engineering AG, SCHLIEREN, Switzerland

This study aimed to clarify the technical aspects of environmental quality standards (EQS) derivation for active substances used in plant protection products. In case studies using six compounds relevant for Swiss surface waters, EQS were derived according to three currently used guidance documents: the Lepper guidance document (Lepper 2005), the Dutch guidance document for deriving EQS (van Vlaardingen and Verbruggen 2007) and the EU draft TGD for EQS (EU 2010). The active substances were: the herbicides Diuron, Mecoprop and Terbuthylazine; the fungicide Carbendazim; and the insecticides Diazinon and Imidacloprid. The EQS derivation consisted of three steps: (i) ecotoxicity data were compiled by database and literature search, (ii) the data were assessed separately for their reliability and relevance according to the guidance given in each of the three guidance documents, and (iii) EQS were derived separately according to each of the three guidance documents.
Although a review of the methods showed that the guidance documents are very similar, a few minor differences were detected, which led to small differences between the EQS values derived in the case studies. However, the differences never exceeded a factor of 3, when the same set of data was assessed by the same hazard assessor.
In contrast, the so-called "expert judgment"had a stronger influence on the EQS derivation. By comparing the derived values with publicly available EQS for the same substances, values differed by up to a factor of 20 due to different weighting of the data or due to the choice of a different assessment factor. Finally, the data validation was identified as a very critical step in the EQS derivation. The assessment of data reliability in all three guidance documents is performed according to the Klimisch scoring system, which allows extensive expert judgment. It is therefore recommended to revise or amend the Klimisch scoring system, since it does not seem to guarantee consistent validation between hazard assessors. It should also be mentioned, that the available data was insufficient for the derivation of an EQS based on the SSD approach for all active substances considered here. This is astonishing for such relatively well-studied PPP, and raises questions regarding the future relevance of the SSD approach in EQS derivation.

[6]CESAM & Departamento de Biologia, Universidade de Aveiro, AVEIRO, Portugal
[7]Centro de Estudos Farmacêuticos, Faculdade de Farmácia, Universidade de Coimbra, COIMBRA, Portugal

The prior objectives of the Water Framework Directive for 2015 converged on the need for implementation of risk management processes to achieve environmental quality objectives, i.e., the 'good ecological potential', also relatively to strongly modified water bodies. For this, it is necessary to characterize environmental risks and, afterwards, implement site-specific risk management processes. In this regard, ecotoxicological bioassays have been recognized as valuable tools for evaluating the ecological impacts of contaminants and the interactions between the biotic and abiotic environment. The aim of the ECOTOXTOOLS project is to implement, evaluate, and validate a battery of short-term bioassays that can be used as sensitive, rapid and simple (i.e., cost-effective) tools for the characterization of ecotoxicological risks due to pesticides and cyanobacteria toxins in Southern Europe big freshwater reservoirs adjacent to intensive agricultural areas, taking as case study one of the worst cases scenarios: the Alqueva reservoir (Guadiana river basin, Portugal). In fact, the high temperatures and low precipitation, with long dry periods, characteristics of the Southern Europe countries, especially those influenced by the Mediterranean climate, dictate slow water renewal and strong evaporation, enhancing the adverse effects caused by excessive inputs of nutrients and by intensive farming practices. The ECOTOXTOOLS project integrates a multidisciplinary team of researchers from Academia, that have been working on the evaluation of the main parameters responsible for the variability of water quality provided by reservoirs in southern Portugal, namely on nutrients, metals and pesticide residues, on incidence and toxicity of algal blooms, and on aquatic ecotoxicology, as well as a main stake-older and end-user: the company that manages the Alqueva reservoir (EDIA), which will be a permanent advisor.

**Development of regulatory testing procedures to study the metabolism of pesticides in farmed fish**

C Schlechtriem[1], P Seymour[2], R Heintze[3], J Benner[2]
[1]Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), SCHMALLENBERG, Germany
[2]Syngenta Limited, JEALLOTS HILL, United Kingdom
[3]Federal Office of Consumer Protection and Food Safety (BVL), BRAUNSCHWEIG, Germany

Information provided for the authorisation of a plant protection product (PPP) must be sufficient to permit an evaluation of the risks for man and (food producing) animals arising from residues of the active substance and relevant metabolites remaining in food and feed. Metabolism studies on food producing animals provide an estimate of PPP residues in edible products and must be performed when a PPP is used in crops from which parts or products are fed to livestock. Metabolism studies on ruminants and poultry are a current regulatory requirement. However, due to the increasing proportion of plant derived materials in aquaculture diets, metabolism studies on (freshwater) fish such as rainbow trout or carp will also be required when PPP of logKow >3 are used in crops fed to farmed fish. Metabolism studies are normally conducted with a suitable radiolabelled form of the active substance to identify the major components of the total residue and to show the efficiency of extraction procedures for these components. Following this initial assessment of the nature of the residues in food commodities, such as meat, milk and eggs, further livestock feeding studies are usually required. These use non-radiolabelled test material and a larger group of animals to provide the data necessary to establish maximum residue levels for food products of animal origin. Available guidance documents on metabolism and feeding studies for ruminants, poultry and pigs are available but these are not fully applicable to fish due to the differences in the animals' environment and husbandry conditions. More specific guidance documents for fish are therefore necessary.
A concept for fish metabolism is described and compared with the established guidance documents for other food producing animals. The results of a study on rainbow trout, designed to assess the practicality of the experimental design and to identify further technical challenges, are presented. The methodology used in the study is anticipated to meet the needs of new regulatory guidelines, which will require an understanding of metabolism and residues in fish farmed for human consumption.

## RA07 - Monitoring data and post-registration studies for PPPs: generation, compilation and use in the environmental risk assessment and management

**MO 367**

**Pesticide usage monitoring of Swiss farms**

SL Spycher, O Daniel
Agroscope Changins-Waedenswil Research Station, ACW, WAEDENSWIL, Switzerland

Until recently trends of pesticide usage in Switzerland were derived from sales data. However, pesticide usage differs strongly between different crops, over the course of the year and between different regions. Such information can only be gained if data on the pesticide usage on farms are collected. Different approaches for pesticide usage data collection exist in Europe: farm visits by trained staff, postal or e-mail surveys, or compulsory returns of pesticide usage data.
In 2009 Switzerland implemented an approach to monitor pesticide usage based on the data collected by farmers in order get subsidies. The data are collected with Agro-Tech, a bookkeeping software. Agro-Tech was extended recently to include environmental indicators like nutrient balance, green house gas emissions, use of veterinary pharmaceuticals, use of pesticides, but also size and quality of ecological compensation areas. The data collected for pesticides give information on the amount of product and the dates of application for different cultures.
The data are valuable for a large number of questions, e.g., the evaluation of plant protection practice, the targeted chemical monitoring of surface waters and also the calculation of ecotoxicological risk indicators. As the data will be collected on a yearly basis, the approach should also allow the distinction of fluctuations due to pest pressure and long term trends due to changes in agricultural practice, a distinction which is much more difficult if surveys are conducted at longer time intervals. A critical issue is the number of participating farms. Ideas to estimate the required sample size for the different cultures are presented.

**MO 368**

**Monitoring crop preferences of birds in arable farmland: importance of oilseed rape for Reed buntings (Emberiza schoeniclus)**

S Steiger[1], R Hare[2], G Hartwell[3], W Mckay[2], J Pascual[1]
[1]BASF, LIMBURGERHOF, Germany
[2]Agricultural Trials Services, GOOLE, United Kingdom
[3]BASF plc., CHEADLE HULME, United Kingdom

The decline of natural habitat in Europe has clearly increased the importance of farmland habitats for birds in recent decades. However, it is still not understood in detail if specific crop types, grown under modern and intensive agricultural practice, are favored as breeding and foraging habitat for different birds. In a long-term field monitoring study, we monitored bird populations at Top House Farm (Rawcliffe Bridge, Goole, East Yorkshire, UK) from 2003-2010. This 142-ha farm, located in intensively managed farmland, employing best practice agronomy, is managed using commercial agronomic techniques under a relatively high-input regime (detailed information on the yearly use of plant protection products is available) and is cropped as a wheat-based rotation. The crops occupying the study area were primarily: winter wheat, winter oilseed rape, spring beans and spring linseed. In each year, four to five bird surveys were carried out between April and July at approximately 3 to 4 week intervals. Here, we focus specifically on the Reed bunting (*Emberiza schoeniclus*), a bird that was on the UK 'red list' of conservation concern, although now moved to the 'amber list'. We show that oilseed rape is the crop in which the highest number of birds and the highest numbers of breeding territories were observed compared to winter wheat or the other crops. Notably, with the absence of oilseed rape at Top House Farm in 2008, the density of Reed buntings substantially declined in that year. Despite the relatively high-input and intensive agronomic regime used at Top House Farm, the densities of Reed buntings on Top House Farm were considerably higher than the UK average. This long-term study strongly supports recent short-term findings indicating that Reed buntings benefit from the inclusion of oilseed rape in the crop rotation and suggests that the inclusion of oilseed rape is an efficient management tool benefiting this bird species. In addition, this monitoring study provides an example of how simple survey methods can be used in monitoring programs to assess bird diversity in fields with standard use of plant protection products.

**MO 369**

**Predicting input of pesticides to surface water via drains - comparing post registration monitoring data with FOCUSsw predictions**

A Aagaard[1], J Kjaer[2], AE Rosenbom[2], P Olsen[3], AL Gimsing[1], S Marcher[1]
[1]Danish EPA, COPENHAGEN K, Denmark
[2]Geological Survey of Denmark and Greenland, COPENHAGEN K, Denmark
[3]Department of Agroecology and Environment, TJELE, Denmark

The environmental risk assessment of pesticides in Europe is based on crop relevant exposure scenarios for the intended uses. A tiered FOCUSsw modelling approach (Step 1-4) is used to provide harmonised exposure data for the aquatic risk assessment. At FOCUSsw Step 3 exposure is modelled in different water bodies (pond, ditch and stream) in 10 scenarios representing geo-climate conditions across Europe. The model provides estimates of surface water concentration, based on the intended use, taking into account potential input routes (drift, drainage and run-off). Leaching and subsequent transport through the drainage system poses an important contamination pathway allowing rapid transport of pesticides to the surface water system. With FOCUSsw this input is modelled via the 1 dimensional root zone model MACRO allowing preferential transport to occur in the unsaturated zone. Although models (such as MACRO) are widely used within the registration process, their validation requires further work, not least because of the limited availability of field data.
The Danish Pesticide Leaching Assessment Programme (PLAP), an intensive monitoring programme which is used to evaluate the risk of leaching of pesticides under field conditions, aims to analyse whether pesticides applied in accordance with granted uses enter the aquatic environment in unacceptable concentrations. Within this programme a high resolution data set comprising 10 years of various pesticide concentrations in drainage from 3 field sites (1.7 - 2.3 ha, sandy loam) are available for model validation. Moreover, a "site specific"setup of the MACRO model already calibrated and validated with respect to water and non reactive solute transport is available from these field sites.
For a sub-set of pesticides representing a range of use patterns and inherent properties (e.g. sorption potential, persistency and toxicity) output from drain to surface water has been assessed from both measured and modelled data. The latter comprising output from the MACRO model parameterised either via the FOCUSsw setup (relevant scenarios) or the "site specific setup"applied at the PLAP sites. Output from monitoring and the two modelling approached are compared and uncertainties of the different approached are discussed. It is considered how monitoring data from post registration systems can be "optimised"in order to improve their usability in risk assessment (e.g. validation of modelling, output format).

**MO 370**

**Constraints in monitoring environmental and health risk management studies - Post registration in INDIA**

V Saini
M/s. Pesticide Regulatory Affairs - INDIA, FARIDABAD ( HARYANA ), India

Pesticides and certain other chemicals classified as dual-use chemicals are primarily regulated by The Insecticides Act., 1968. Registration process of such chemicals are granted after adhering to a stringent and exhaustive set of guidelines framed for various categories of registration. Incidentally, once a product has been granted registration, post-registration monitoring is practically missing. Review of such chemicals take place depending upon its use pattern and subject to any international concern. However, a well planned scientific and regulated post-registration is not mandatory, neither at the national or state level. This is primarily due to lack of enforcement of legislations and proper timely coordination. Communication of decisions and its implications are generally waived by various departments on the pretext of their own dedicated authority. Risk assessment in a broad sense is missing due to lack of responsibility and an commitment towards the society and nation as a whole. Interesting facts and case studies will be revealed in this paper and make an attempt to give an overview of the issues involved in country where legislations are in the plenty but enforcement and implementation are lacking.

**MO 371**

**ASTERisk, a tool to assess the pesticide risk**

F Galimberti[1], T Mammone[1], G Azimonti[1], A Moretto[2], E Andreini[3]
[1]International Centre for Pesticides and Health Risk Prevention - ICPS, MILAN, Italy
[2]Università degli Studi di Milano, MILAN, Italy
[3]Azienda Ospedaliera - Polo Universitario "L.Sacco", MILANO, Italy

The planning of controls on pesticide retails and farms carried out by Regional Local Health Units in Italy is not homogeneous and is not tailored on local specificities. This entails a less than efficient use of time, human resources and budget, but above all, a less effective risk assessment and prevention for human health and the environment.
The International Centre for Pesticides and Health Risk Prevention (ICPS) supports the Health Directorate of the Region Lombardy, to achieve the sustainable use of pesticide by developing preventive and safety programmes and by collecting and managing pesticide sale datasets at sub-Regional scale.
ICPS developed a tool, a suite of different databases including information about pesticide loads as sold yearly in Lombardy Region, from certified European and National sources on toxicity, fate, ecotoxicity characteristics of pesticides, and data on geo-referenced crops and underground waters. This tool, called ASTERisk (the acronym stands for a Tool to ASsess the pEsticide Risk) is able to address prevention activities planned by the public administration by providing mainly:
- risk assessment of the general population and farmer exposure to the most sold pesticides in Lombardy Region;
- identification of the areas at higher environmental risk after agricultural use of pesticides.
In addition, ASTERisk may provide, through the use of some ad hoc qualitative indicators, some hints to assess the selection pesticide stores and in agricultural farms to be inspected and monitored.
From a normative point of view, ASTERisk meets the requirement of the Regional law N.8 "Disposizioni in materia di attività sanitarie e socio- sanitarie"(April 2007) requests, which aim primarily at ensuring a higher protection of the citizen's health right through an integrated system of prevention and control. In addition, ASTERisk is relevant also for the "Piano di controllo ufficiale su commercio ed impiego dei prodotti fitosanitari per il quinquennio 2009-2013", a recent legislative (April 2009) issued by the Conferenza permanente per i rapporti tra lo Stato, le Regioni e le Province autonome di Trento e Bolzano. In this case, the opportunity to have all data and information on pesticide characteristics, pesticide retails and farms in a unique tool allows the public administration to manage and easily comply with the legislative and bureaucratic requirements, about risk assessment of pesticide stores and users.

**MO 372**

**Assessment of lambda-cyhalothrin in vegetables: case study of Nairobi City, Kenya**

KG Joyce[1], MI Jane[1], WN Ruth[2], TL Thoruwa[2]
[1]University of Nairobi, NAIROBI, Kenya
[2]Kenyatta University, NAIROBI, Kenya

Vegetables are essential in the diet for they provide, fibre, trace minerals, vitamins, folacin, carbohydrates and protein. However, pests, diseases, and weeds destroy vegetables. As such many pesticides have been developed to control pests. Most of them are poisonous to creatures besides those they are intended to kill and can be harmful to the human health. Although vegetables are widely consumed by almost everybody in Kenya, there is little work reported on the analysis of pesticide residues in them. In this study lambda-cyhalothrin was analysed in selected vegetables which included; kales, cabbages and tomatoes. Lambda-cyhalothrin is an insecticide which is commonly used on vegetables and other crops. Similar vegetables from different markets were then homogenized to give analytical samples. Lambda-cyhalothrin residues were extracted from the samples using organic solvents. The lambda-cyhalothrin residues were then determined by high performance liquid chromatography (HPLC). The data derived was analysed statistically using t-test and regression analysis. The lambda-cyhalothrin mean residue levels ranged from $0.0300\pm0.0100$ to $0.3400\pm0.1100$ mg/kg during the dry season and from non-detectable level to $0.0040\pm0.0090$ mg/kg during the wet season. The study showed that, during the dry season lambda-cyhalothrin residue levels were significantly higher than during the wet season in the vegetable samples analysed. During the dry season the lambda-cyhalothrin mean residue levels in the vegetable samples were higher than the Acceptable Daily Intake (ADI) of 0.02 mg/kg, although most of them were lower than the Maximum Residue Levels (MRLs) of 0.2 mg/kg except in tomatoes. During the wet season the lambda-cyhalothrin mean residue levels were all lower than both the ADI and MRLs.

## RA12 - Risk communication for environmental protection: Scientific and regulatory needs

**MO 375**

**Tools of communication about chemicals in the contest of the REACH implementation**

S Lupi[1], SS Santoro[2], CZ Zaghi[1]
[1]Italian Ministry of environment, land and sea, ROMA, Italy
[2]National Research Council (CNR) - Institute of Atmospheric Pollution Research, ROMA, Italy

For the implementation of the REACH Regulation (Registration, Evaluation and Authorisation of Chemicals), the Italian Ministry for the environment, land and sea has the task to give information about the risks of chemicals, involving also consumer and environmental organizations. Therefore, in July 2010, the publication of the e-bulletin "Sostanze chimiche - Ambiente e

Salute"was undertaken. It deals with activities and news related to REACH, other Regulations concerning chemicals and risk mitigation measures. The aim is to provide through a simple language adequate information for the public on risks and safe use of chemicals, dealing with specific items in each e-bulletin.
In addition to the main topic of the e-bulletin it has been prepared:
- an 'Events' section about meetings, seminars, workshops on technical legal issues relating to chemicals;
- a 'News from ECHA' section containing details of the main procedures of public consultation launched by ECHA (European Chemicals Agency), about proposals for restrictions and/or inclusion in the "Candidate List of Substances of Very High Concern";
- a "Link"section.
To manage the registration and sending the newsletter a dedicated mailbox is created. The address is sostanzechimiche@minambiente.it.
An e-mail with the first issue of the bulletin and the registration form to receive future issues was sent to:
- Environmental organizations;
- Consumer organizations;
- Regional Environmental Protection Agencies;
- Regions (Environment and Health Departments);
- National Technical Committee for the REACH implementation;
- Regional authorities of vigilance.
The Ministry should also promote activities to ensure public access to information on chemicals through the creation of databases that allow easy access to information on hazardous properties of substances.
For this purpose the database DESC (Database Ecotossicologico sulle Sostanze Chimiche) was created. It contains the main ecotoxicological and environmental information of more than 650 chemicals manufactured and/or imported into the European market. The database is structured to be implemented and to contain an unlimited number of substances. Moreover it's in Italian language, to facilitate consultation by not expert public.

**Magnifying Perceived Risk: how misconceptions about the importance of ethinyl estradiol (EE2) to the overall endocrine disruptor issue is driving misguided risk management decisions**
J Mastrocco[1], DJ Caldwell[2], P Anderson[3]
[1]PFIZER INC, NEW YORK, United States of America
[2]Johnson+Johnson, NEW BRUNSWICK, United States of America
[3]ARCADIS US Inc, Chelmsford, United States of America
'Selective' reporting and exaggeration have resulted in undue concern over environmental presence of EE2. Inaccurate or snapshot field measurements used as 'environmentally-relevant' test concentrations in laboratory studies, biomarker detection (i.e., vitellogenin in male fish) incorrectly reported as effect, and field experiments using confined exposure (i.e., lake) being inappropriately extrapolated to surface water (river) risk assessments have all contributed to the misconception that EE2 exposure is of great consequence to wildlife and humans.
With the media always placing contraceptives at the top of the list when discussing the endocrine issue, the regulatory community is being swayed to take unwarranted risk management actions with potentially costly consequence. A detailed review of monitoring and effect data show that fish exposures are largely at or below sensitive predicted no effect concentrations and that human exposures are miniscule when compared to other estrogens in the diet. All of which support the contention that undue attention is being paid to EE2 and that overall estrogenic exposure is the appropriate determinant when considering this aspect of endocrine disruption.

**MO 377**
**The Maximum-Allowable-Daily-Loss (MADL) Report: a site-specific manufacturing risk communication tool for industry**
J Mastrocco, C Smith
PFIZER INC, NEW YORK, United States of America
Through the application of a database structure designed to organize information in a highly accessible, parsed format and an automated report generating protocol capable of gathering, filtering, and manipulating data we deliver a detailed, site- and substance-specific report describing inherent hazard , PBT profile, estrogenic potential, and risk-based MADLs for manufacturing facility consideration. The MADL incorporates site characteristics to transform the traditional PEC/PNEC assessment into a mass loss below which no adverse impacts are expected. Separate MADLs are calculated for WWTP function, focusing on bacterial inhibition and for local receiving waters, focusing on indigenous or representative organisms. In addition, a 'stoplight' risk analysis matrix is supplied to point out the parameter(s) driving the risk so that informed decisions can be made for future testing strategies.
The MADL report can be used to support site selection, WWT enhancements, or waste stream diversion. While useful for understanding individual compounds, future enhancements will consider coexisting substances to report combined risk.

**Challenges of the EU REACH regulation: a perspective from British American Tobacco (BAT)**
NG Rehman, JK Scott, I Crooks
British American Tobacco, SOUTHAMPTON, United Kingdom
This poster presentation describes some of the challenges faced by BAT, in interpreting the new EU REACH regulation. Ingredients are added to the tobacco depending upon the product type which can be single substances on their own or in preparations. Under REACH, BAT is an importer and a downstream user (DSU), and not a manufacturer of such substances.
A cigarette is a "preparation in a container"with the container considered to be an 'article' under the scope of REACH. 'Articles' include non tobacco materials such as cigarette papers and filters, manufactured in (or imported into) the EU for use in BAT products. Substances in articles or preparations may require registration depending on the criteria defined in the regulation for example if they are present in quantities exceeding one tonne per producer or importer per year. REACH also identifies specific exemptions as defined in Article 2, Annex IV and Annex V.
A REACH evaluation screening process has been developed within Group Research & Development (GR&D) as a simple and effective method for identifying REACH compliance requirements for tobacco ingredients. Key elements of the REACH screen include 1) Annex IV exemption 2) Annex V exemption 3) Tonnage and 4) Registration and Pre-registration status. This process has been documented as a flow chart with decision codes and outcomes. Key learnings and experiences of implementing the REACH screen are presented in this poster.

**Environmental risk assessment outputs for socioeconomic analysis under REACH**
C Simpson[1], DH Leverett[1], H Stolzenburg[2], M Crane[1]
[1]WCA environment, FARINGDON, United Kingdom
[2]Umweltbundesamt, DESSAU, Germany
The outputs from environmental risk assessments (ERAs) are not the same as the "impact assessment"information required for socioeconomic analysis (SEA), making it difficult to develop Restrictions and Authorisations under REACH. ERA outputs are usually in the form of Risk Characterisation Ratios (RCRs), in which a PEC is divided by a PNEC. If the RCR is >1 then a potential risk is assumed. However, SEA requires the translation of an RCR or its underpinning data into a "value". Translating RCRs into an assessment of impact requires further, ideally quantitative, information on how severe and extensive any effects are likely to be in the real world, our level of certainty about these effects, and how different risk management measures might alter this risk. ECHA has identified the following additional problems in translating ERA outputs into SEA impacts: 1) a chemical's persistence is a key reason for concern about its presence in the environment, but this persistence makes it difficult to quantify any changes in impacts over time; 2) chemical persistence gives rise to trans-boundary issues, complicating both the quantification of effects and any attempts to value such effects ( "whose values"should be assumed?); 3) an absence of environmental monitoring data (together with transport, fate and behaviour data in some cases) to establish the geographic extent of environmental concentrations above the no effects level; 4) difficulties in linking toxicity data for sensitive species to other species or ecosystem effects; 5) combinations of sources contributing to environmental concentrations, leading to difficulties in determining how restrictions on some uses would affect concentrations in the environment; and 6) significant variations across the EU in the processes used, the continuous or sporadic nature of use and emissions, and in existing levels of treatment. This poster presents examples of potential ways to translate ERAs into environmental impacts which can be practically used to inform SEA and eventual decision making under REACH. These approaches include: 1) exposure-based "proxies"of effect, such as changes in volumes of exposed media, as generated by probabilistic EUSES modelling; 2) use of species sensitivity distributions and the dose-responses of sensitive species; 3) read-across from similar substances for which there is more information; 4) Life-cycle Impact Assessment; and v) the ecosystem services concept.

**Communication - a tool to reduce the exposure of pharmaceuticals in the environment!**
N Amato[1], n Götz[2], n Deffner[2], n Rechenberg[1]
[1]Federal Environment Agency, Germany, DESSAU-ROSSLAU, Germany
[2]Institute for Social-Ecological Research, FRANKFURT ON THE MAIN, Germany
Human pharmaceuticals mainly enter the environment via domestic wastewater. Although concentrations are usually very low, first impacts on aquatic organisms have been detected. One important step to reduce the entry of pharmaceutical residues into the environment is to improve the awareness of specific target groups within the health care system: the public, the physicians and the pharmacists respectively. For this reason the Federal Environment Agency, Germany (UBA) and the Institute for Social-Ecological Research (ISOE) prepared recommendations for a communication strategy. The current knowledge of the specific target groups and factors, affecting the handling of pharmaceuticals has been identified, revealing that the problem of pharmaceutical residues in the environment is widely unknown. Therefore the first objective was to create profound knowledge. This sensitisation is the basis for implementing further strategies leading to raise awareness and initiate behavioural changes. Modifications will affect daily routines concerning medication such as prescription, compliance, non-medicamentous prevention as well as patient-doctor-interaction. Moreover the results of the project clearly reveal that the knowledge, the handling and the reflection of the subject pharmaceuticals in the environment varies not only between, but also within the individual groups. This means that a promising communication strategy has to be tailored to the individual needs in the specific target groups. This strategy also contains the communication of a proper medication disposal and is intended to promote the return of all unused medication by implementing a feasible take-back scheme. The strategy is also to emphasise that under any circumstances pharmaceuticals should not be flushed down the toilette or the sink and by this get into the water circle. Based on an analysis of typical shortcomings in available publications, the project compiled recommendations for conceptualizing information material.

**Chemical risk communication from the ecodesign perspective: legislative preconditions and needs for more information than required by law**
J Simanovska, K Valters, G Bažbauers
Riga Technical University, RIGA, Latvia
Ecodesign or design for the environment is a systematic design approach to reduce environmental impacts of products and to achieve higher protection standards than set by law.
